Bone marrow involvement by FL is seen as large, usually circumscribed nodules adjacent to bony trabeculae (**Fig. 17-9C–E**).[57] This feature is useful in distinguishing nodules of lymphoma from benign lymphoid aggregates, which are usually central within marrow spaces rather than paratrabecular; however, occasional paratrabecular lymphoid aggregates can be seen in apparently healthy individuals.[57] Infiltrates that appear to hug or wrap around bony trabeculae are highly suspicious for FL, in contrast to those that simply touch the trabeculae. Marrow aggregates of FL are typically composed predominantly of small centrocytes (**Fig. 17-9D**), with

only rare centroblasts; the cellular composition may not reflect that of the lymph node, which may contain larger centrocytes and more centroblasts. Marrow involvement by centrocytes can be seen in cases of DLBCL—so-called "discordant" bone marrow histology.[62] Thus, lymphomas cannot be accurately subclassified based on their appearance in the bone marrow, as this may not reflect the appearance of a nodal tumor.

Peripheral Blood

Most patients with FL have small numbers of circulating neoplastic cells without an elevated lymphocyte count, which can be detected by flow cytometry or molecular genetic analysis to detect the t(14;18).[63-65] Rare patients with FL have an elevated lymphocyte count with circulating centrocytes, which are usually slightly larger than small lymphocytes and have a nuclear cleft (**Fig. 17-9F**). Absolute lymphocyte count ranges from 1000 to >200,000/μL.[12,66] Patients with FL presenting with a leukemic phase often have a high-risk FLIPI score (see section titled "Prognosis and Predictive Factors").[12] FLs with a leukemic phase appear to behave in a more aggressive manner than those without,[12,66] with shorter progression-free survival and overall survival (OS).[66] The morphology of the circulating cells is similar in follicular and mantle cell lymphoma, and some cleaved cells may be seen in occasional patients with chronic lymphocytic leukemia. Immunophenotyping by flow cytometry and often lymph node biopsy is typically necessary for correct subclassification.

Related B-Cell Lymphomas and Follicular Proliferations

See **Box 17-1**.

Pediatric-Type Follicular Lymphoma

When FL occurs in children and adolescents, it often has clinical and pathologic features distinct from those of FL in adults. Although rare, germinal-center derived lymphomas occurring in the pediatric age group appear to be composed of several entities. Among these is pediatric-type nodal FL, designated as a variant of FL in both the ICC and WHO 5th edition classifications.[1]

Pediatric-type FL (PTFL) is a localized neoplasm of germinal-center B-cells with an entirely follicular pattern that occurs in the lymph nodes of children and young adults (**Fig. 17-10**). PTFL mainly affects young patients with a median age of onset of 15 to 17 years.[67,68] There is no upper age cut-off for diagnosis; the majority of patients range in age from 5 to 30 years.[67-70] Cases with features of PTFL have been identified in patients older than 40 years of age, but these are rare.[70] PTFL predominantly affects male patients (M:F = 10:1).[67-69] PTFL is virtually always localized (stage I) and most commonly presents in the lymph nodes of the head and neck.[67-69] Cases have an entirely follicular pattern with expansile and/or serpiginous follicles that, at least partially, efface the nodal architecture. Evidence of marginal zone differentiation is common, and may be the predominant component in some cases (see Chapter 20). There is often a rim of residual normal lymph node architecture at the periphery of the involved node, imparting a “node in node” appearance. As seen in usual FL of older adults, follicles often have

attenuated mantle zones. Follicles often consist of a monotonous population of intermediate-sized blastoid cells that are distinct from both centrocytes and centroblasts.[68] Tingible body macrophages are often present. The neoplastic cells are CD20-positive CD79a-positive PAX5-positive B cells with consistent expression of BCL6, and a high proliferation fraction of >30% by staining for Ki-67. Cases usually are mostly positive for CD10 and usually do not express BCL2, but they sometimes show faint BCL2 staining in a subset of neoplastic B cells.[67-69] Staining for IRF4/MUM1 is usually negative. Follicles are associated with CD21-positive and CD23-positive FDC meshworks. Cases of PTFL do not show rearrangements or amplification of *BCL2, BCL6, IRF4,* or Ig loci. FISH for these gene rearrangements should be routinely performed, as the presence of any of these rearrangements rules out the diagnosis of PTFL. Approximately 60% of PTFL cases harbor mutations in *MAPK* pathway genes (including *MAPK1*), which are not present in classic FL. In addition, PTFL shows recurrent deletions and copy-neutral loss of heterozygosity at 1p36 in addition to *IRF8* mutations in a subset of cases. PTFL lacks mutations in chromatin-modifying genes and other genes commonly mutated in classic FL, such as *CREBBP, KTM2D, EP300,* and *ARID1A*. Both PTFL and classic FL harbor mutations in *TNFRSF14* in less than 50% of cases.[71] PTFL, when diagnosed according to the criteria listed in **Table 17-4**, has an excellent prognosis with a 5-year survival of over 95%. There is growing evidence that local excision of PTFL diagnosed in children may be sufficient treatment, with no evidence of subsequent progression or relapse. Retrospective studies have shown that young adults diagnosed with PTFL have a similar excellent prognosis irrespective of therapy, though the majority of

adult patients reported have received systemic chemotherapy or radiation therapy.[67,68]

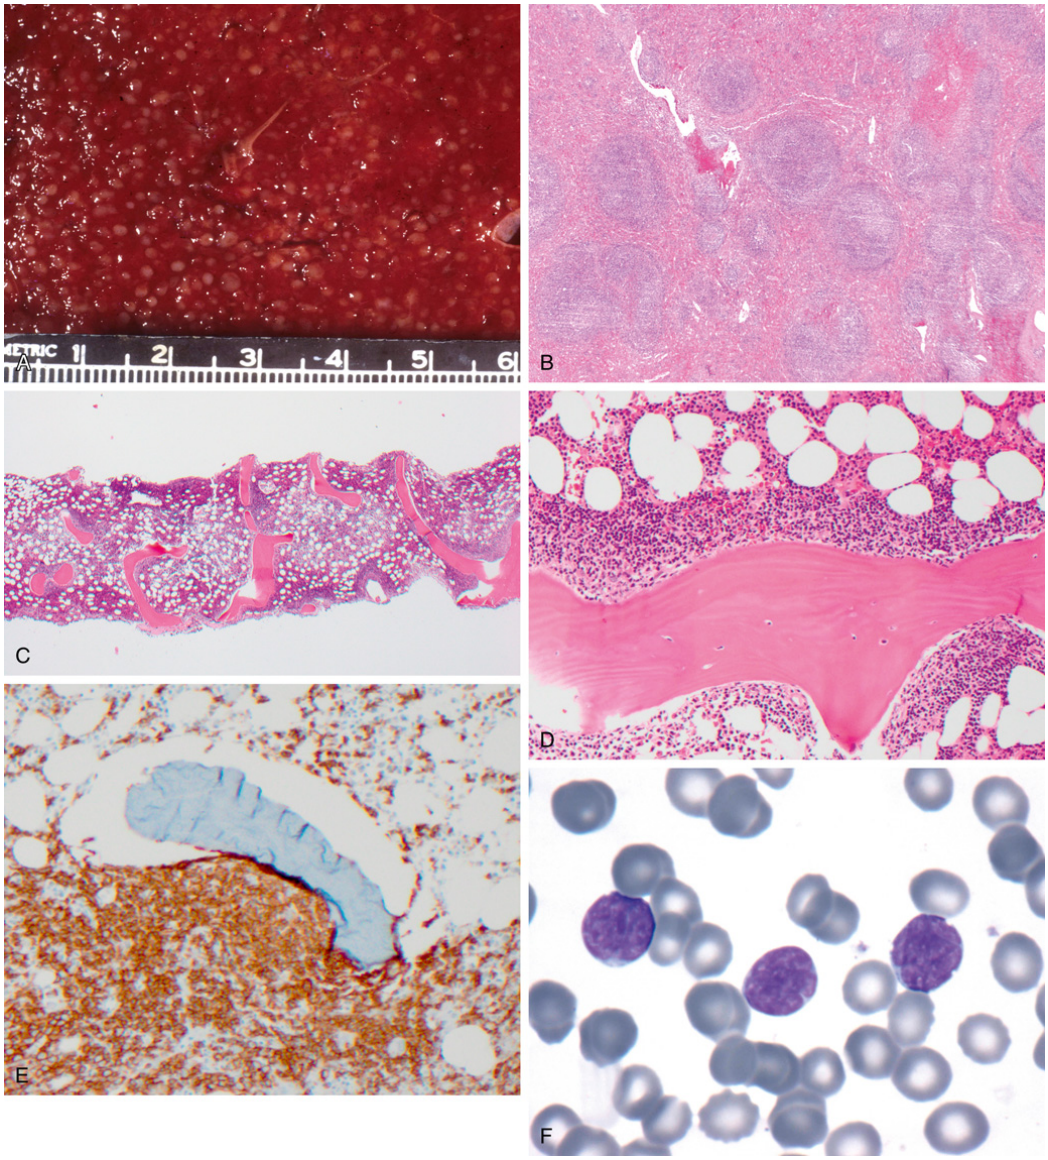

FIGURE 17-9 Appearance of follicular lymphoma (FL) in the spleen, bone marrow, and peripheral blood.A, In this gross photograph of a spleen involved by FL, nodules of white pulp are increased in size and number, and most are relatively round. **B,** In a low-power photomicrograph of FL in the spleen, white-pulp follicles are enlarged and increased in number; preserved marginal zones are present

around some of the neoplastic follicles. **C,** In this bone marrow trephine biopsy, a broad cuff of neoplastic lymphoid cells surrounds many bony trabeculae. Residual normal hematopoietic marrow is present, away from the bone, and is recognizable as areas with a normal distribution of fat. **D,** At higher magnification, there is a predominance of centrocytes. **E,** Immunoperoxidase stain for CD20 confirms that they are B cells. **F,** A peripheral blood smear from a patient with FL shows circulating centrocytes with prominent nuclear clefts (Wright's stain).

tumor cells are negative for BCL2. **E,** They have a high proliferation fraction.

Lymphomas with *IRF4* rearrangement (discussed separately) often affect children and may have a follicular pattern[72]; however, lymphomas with *IRF4* rearrangement represent a different entity and are excluded from the category of PTFL.

Extranodal Follicular Lymphomas

In addition to primary cutaneous follicle center lymphoma[73] and duodenal-type FL,[74] other extranodal sites of FL presentation include Waldeyer's ring,[75] testis,[76,77] ocular adnexa,[78] salivary glands,[79] thyroid,[80] gallbladder and extrahepatic biliary tract,[81] female genital tract,[75] and others. A minority of FLs show primary extranodal involvement without systemic disease. Primary testicular FL is rare and shares many pathologic and clinical features with pediatric-type FL. Testicular FL typically affects young boys, presents with localized disease with BCL2-negative neoplastic germinal center cells, lacks *BCL2* rearrangement and has an excellent prognosis.[76,77,82] On this basis, the 2022 ICC has designated primary testicular FL as a provisional entity. Primary extranodal FL arising in the thyroid, conjunctiva, ovary, and lower female genital tract often lacks BCL2 expression and mutations in chromatin-modifying genes frequently mutated in classic nodal FL. Several cases of primary conjunctival FL reminiscent of pediatric-type FL have been described in the literature. These cases show an expansile follicular proliferation, lack *BCL2* rearrangements and conventional chromatin-modifying genes, harbor *MAP2K1* mutations, and remain localized to this site of presentation. Taken

together, extranodal FL tends to present with localized disease, expresses BCL2 less often, has a translocation involving *BCL2* [t(14;18)] less often, and tends to have better survival than nodal FL.[75] However, the characteristics of FL appear to vary somewhat from one site to another.[70,72,76,82,83]

Table 17-4

* Common features of PTFL, but not required

† Any component of diffuse large B-cell lymphoma (DLBCL) or presence of advanced stage disease excludes pediatric-type follicular lymphoma.

Large B-Cell Lymphoma With *IRF4* Translocation

A small proportion of all LBCLs have a translocation involving *IRF4* and an Ig gene (**Fig. 17-11**). LBCL with *IRF4* gene rearrangement is currently considered a definite entity in both the ICC and WHO 5th edition. LBCL-IRF4 most commonly occurs in children and young adults (median age 12 years). These lymphomas usually have at least a partial follicular pattern, but may be entirely diffuse.[72] Therefore, patients with high-grade FL expressing IRF4/MUM1 should be evaluated for IRF4 alterations.

LBCL-IRF4 shows a predilection for head and neck sites, including Waldeyer's ring, and often present with limited-stage disease.[70,72,83a] Immunophenotyping shows that neoplastic cells are CD5−/+, CD10+/−, BCL6+, BCL2+/−, and MUM1+. In contrast to the vast majority of FLs, they lack *BCL2* rearrangement. They often harbor *BCL6* rearrangements. They appear to be associated with a

favorable outcome, even if predominantly diffuse. Aggressive B-cell lymphomas with *IRF4* rearrangements associated with *BCL2* or *MYC* rearrangements are excluded from this category. LBCL-IRF4 translocation is a distinct entity from pediatric-type FL, which has previously been discussed.

Duodenal-Type Follicular Lymphoma

Duodenal-type FL is a distinct and uncommon clinicopathologic entity, comprising fewer than 4% of all primary GI lymphomas.[13] In one study of 222 GI lymphomas, 13 duodenal lymphomas and 8 FLs were identified: five of the eight FLs arose in the duodenum, all in its second portion, in the vicinity of the ampulla of Vater.[13] This and subsequent studies have revealed that patients with duodenal-type FL are mostly middle-aged adults with a mean or median age in the fifties[14,74,84] and a female preponderance in most series.[74,85,86] The small intestine is most often involved; the duodenum is the portion most commonly involved,[74,86] although the stomach and colorectum may be affected. On endoscopy, nodularity of the mucosa is the most common finding; cases with the appearance of multiple lymphomatous polyposis have also been described.[74,87] Taken together, the results of these studies suggest that a high proportion of duodenal lymphomas are FL and that a high proportion of GI FLs arise in the duodenum. Duodenal-type FL is typically localized and associated with excellent prognosis. At last follow-up, nearly all patients are alive, with the majority free of disease.[74,87,88]

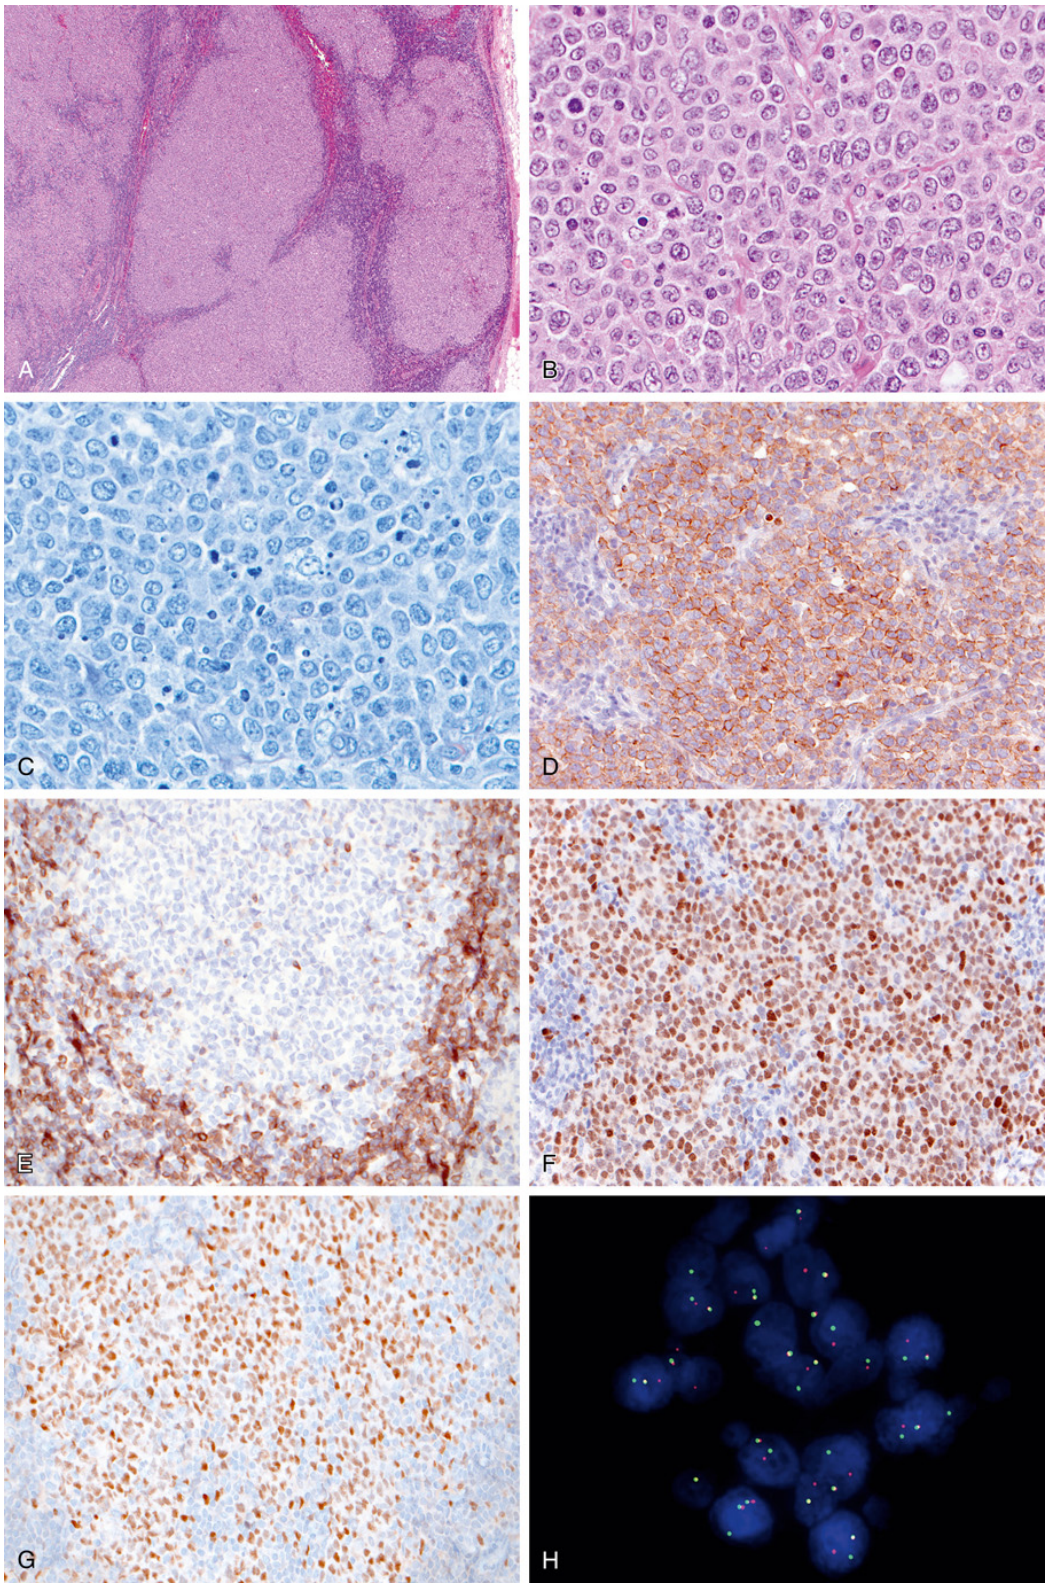

FIGURE 17-11 Follicular lymphoma with translocation involving IRF4.A, An enlarged

submandibular lymph node in a 71-year-old male patient shows a lymphoid proliferation with a jigsaw-like pattern. **B,** The lymphoma involves large centroblastic cells with both mitoses and apoptotic bodies. **C–F,** The lymphoma cells were CD20 positive *(not shown)*, CD10 positive **(D)**, BCL2 negative **(E)** and positive for both MUM1 and BCL6 (**F** and **G**). **H,** Fluorescence in situ hybridization (FISH) studies demonstrate an *IRF4* (6p25) break (homemade probe, telomeric BAC probe SpectrumOrange CTD-2308G5, centromeric BAC probe SpectrumGreen CTD-3139L20), though no breaks were detected for *BCL2, BCL6* or *MYC (not shown)*.

On microscopic examination (**Fig. 17-12**), the vast majority of duodenal-type FL is low grade (**Fig. 17-12A and B**). The cases typically have an immunophenotype similar to that found in nodal FLs occurring in adults (CD20+, CD10+, BCL2+, BCL6+) (**Fig. 17-12C and D**).[14,74,85,86] IGH and Ig light-chain genes are clonally rearranged, and *BCL2* rearrangement is identified in most cases.[85,89,90] In-depth evaluation of these lymphomas does reveal some pathologic features that diverge from those of lymph nodal FL, however. GI FL frequently expresses α4β7, the mucosal homing receptor, suggesting an origin from antigen responsive B cells residing in intestinal mucosa.[91] One study described that, in contrast to lymph nodal FLs, intestinal FLs are associated with "hollowed out," rather than intact, FDC meshworks (**Fig. 17-12E**).[90] The proliferation index is typically low (**Fig. 17-12F**). Intestinal FLs are

reported to lack expression of activation-induced cytidine deaminase *(AID)*.[90] Biased usage of IGH variable region genes (IGHV) has been described, with disproportionate use of *VH4*, in particular *VH4-34*.[84,90] These observations suggest subtle differences in the pathologic features of intestinal and lymph nodal FL; they also suggest an antigen-driven component in the pathogenesis of intestinal FL.[84,90]

Other Extranodal Follicular Lymphomas

In Situ Follicular Neoplasia (ICC)

In situ follicular neoplasia (ISFN) ("in situ follicular B-cell neoplasm", see **Table 17-2**) designates an unusual condition in which follicles containing abnormal, clonal, BCL2 brightly positive cells are present on a background of architecturally normal lymphoid tissue.[43] Relatively few cases have been reported, but patients have been mostly middle-aged or older adults, with men and women both affected.[43,92-94]

On microscopic examination (**Fig. 17-13**), affected lymph nodes closely resemble reactive lymph nodes, except that some follicles may have monotonous-appearing follicle centers composed predominantly of centrocytes within mantles that are typically intact. These monotonous follicles have an immunophenotype like that of other FLs, except that BCL2 is almost always very bright (considerably brighter than the aberrant BCL2 expression found in typical FLs). Occasionally, the abnormal follicles histologically resemble reactive follicles and are only recognizable as abnormal because of the strong BCL2 expression.[43,92-94] The number of abnormal follicles varies from case to case, but typically, not all

follicles in the involved lymph nodes are abnormal. In addition, some follicles are only partially replaced by abnormal follicle center cells. Flow cytometry detects a clonal population in about half of all cases.[93]

Clonal IGH rearrangement and *BCL2* rearrangement are present in most cases, although detection using microdissected tissue or combined immunohistochemistry and FISH appears to be more sensitive than detection using whole sections of tissue, as the abnormal cells are present in relatively small numbers.[43,92,95] In patients with both ISFN and overt FL, the two share common IGH rearrangements and *BCL2* breakpoints, indicating they are clonally related.[95] However, ISFN has few or no copy number alterations when evaluated by comparative genomic hybridization (CGH), which is in contrast to overt FL.[95] *EZH2* mutations are also identified in a subset of ISFN, supporting the concept that *EZH2* mutations are an early change in the development of FL in at least some cases.[95] ISFN must be distinguished from partial involvement by FL (pFL), in which there is architectural distortion but only partial nodal involvement by lymphoma and some residual reactive follicles. Compared with other FLs, pFL usually presents with localized disease,[94,95] but it is more likely to be associated with progressive disease than ISFN.[94,95]

A subset of patients has a prior history of FL.[93-95] An additional subset has concurrent FL or another lymphoid neoplasm, sometimes in the form of a composite lymphoma.[43,92-95] Most patients with isolated ISFN remain well on follow-up without further therapy.[93,94] It is possible that ISFN represents a preneoplastic change or a very early stage in the development of FL that may or may not progress to

clinically evident lymphoma. In cases of ISFN, an outright diagnosis of FL should not be made; the pathology report should indicate that the significance of the finding is unknown and that clinical evaluation for evidence of overt FL elsewhere is suggested.

Florid Follicular Hyperplasia With Clonal B Cells

Rare cases of florid follicular hyperplasia, particularly in young boys, may have clonal populations of $CD10^-$positive B cells detected by flow cytometry and molecular genetic analysis; a diagnosis of lymphoma should not be made in the absence of morphologic features of malignancy.[96] There may be a morphologic overlap between so-called follicular hyperplasia with clonal B cells and PTFL.[96] In the context of this overlap, architectural effacement supports a diagnosis of PTFL.

Immunophenotype

FL B cells express pan-B antigens (CD19, CD20, CD22, CD79a, PAX5) and surface Ig with light-chain restriction. Flow cytometry is usually required to demonstrate Ig expression; occasionally, it can be detected by immunohistochemistry (**Fig. 17-14A–E**). In more than 50% of cases, the surface Ig is μ heavy chain, with a minority also expressing δ; a large minority express γ heavy chain, and rare cases express α heavy chain.[97] The frequency of IGH class switching is higher in FL than in other low-grade lymphomas, consistent with the observation that IGH class switching normally occurs in the germinal center. Most cases express the germinal-center–associated protein CD10 (**Fig. 17-14F**); CD10 expression is often stronger in neoplastic follicles than in reactive germinal centers.[32,97,98] FL also invariably

expresses nuclear BCL6 protein in at least a proportion of the tumor cells.[99] In normal germinal centers, virtually all cells are BCL6 positive, whereas a variable proportion of cells are BCL6 positive in FL (**Fig. 17-14G**). Both CD10 and BCL6 may be downregulated in interfollicular neoplastic cells and in areas of marginal zone differentiation (**Fig. 17-2E**).[32,97,98] A novel marker of germinal-center cells—GCET-1, also known as *centerin*—was discovered by gene expression analysis; it is consistently detected in FL and other lymphomas of germinal-center B-cell derivation.[100]

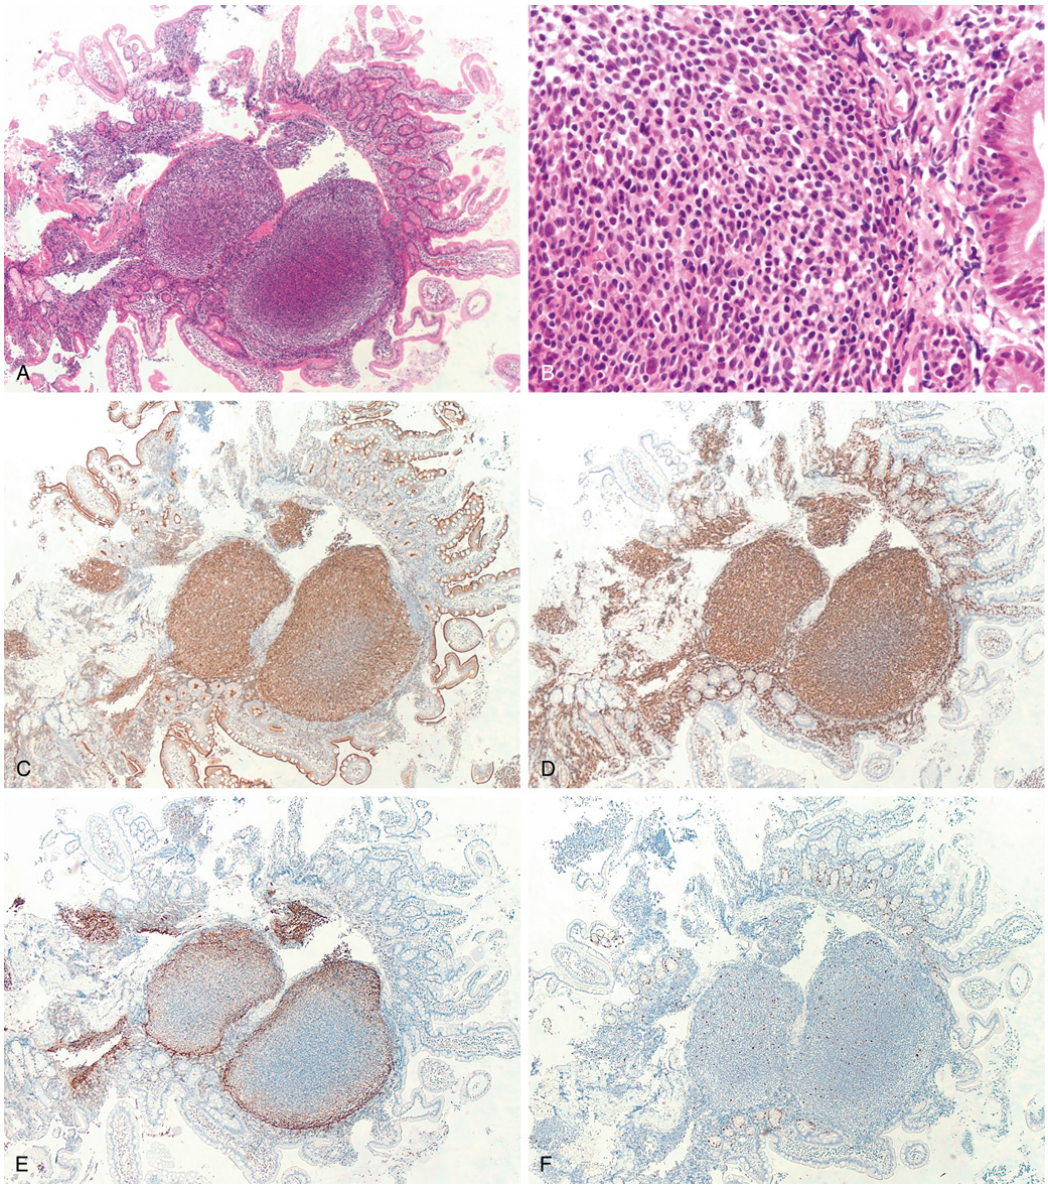

FIGURE 17-12 Follicular lymphoma of the duodenum.A, At low magnification, monomorphous follicles lacking mantle zones are present in the lamina propria. **B,** At higher magnification, there is a monotonous population of centrocytes. The cells are positive for CD10 **(C)** and BCL2 **(D)**. **E,** CD21 highlights a follicular dendritic cell meshwork concentrated at the

periphery of the follicles *(hollowed out pattern)*. **F,** The proliferation fraction highlighted by Ki67 immunostaining is very low.

FL is typically CD5 negative and CD43 negative.[101-103] Rare cases of CD5-positive FL have been reported.[104] Most CD43-positive cases are grade 3, with areas of DLBCL.[103] MUM1/IRF4 is typically not expressed, although occasional cases of grade 3 FL that lack CD10 and BCL2 and express MUM1/IRF4 have been reported.[105,106] FL typically expresses the CD95/Fas protein.[107] FL also expresses costimulatory molecules CD80, CD86, and CD40.[32,108] Expression of these antigens is weak compared with that of normal germinal-center B cells.[108]

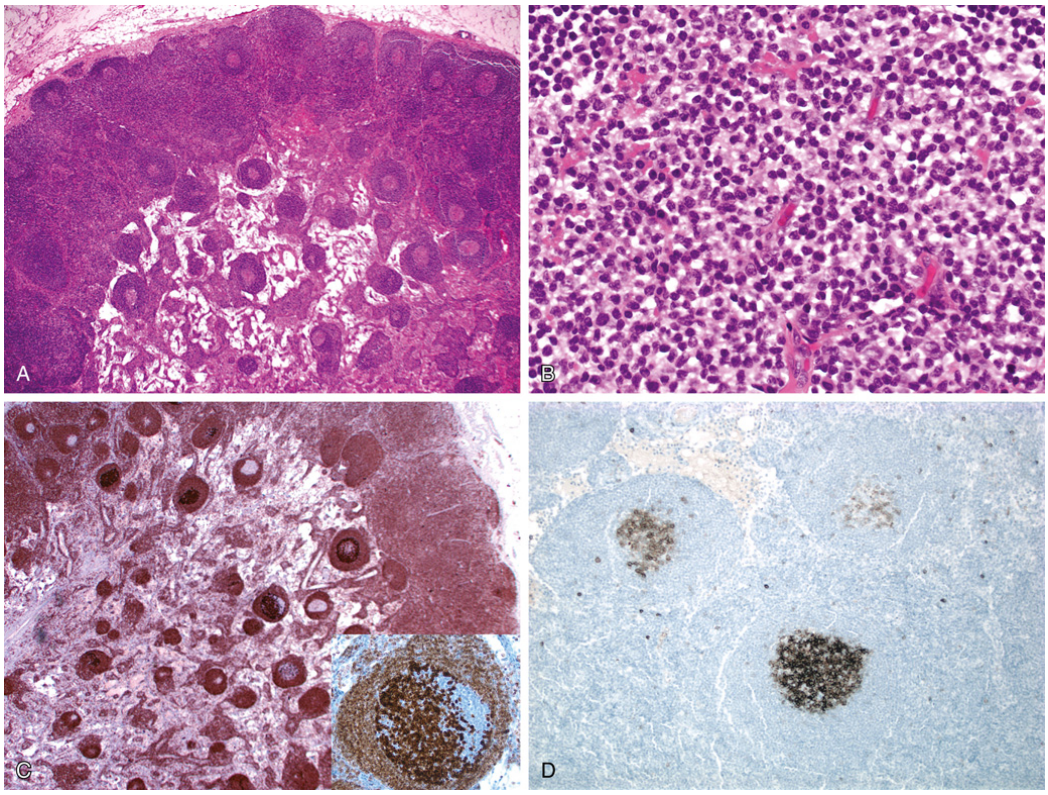

FIGURE 17-13 In situ follicular neoplasia (in situ follicular B-cell neoplasm, WHO 5th edition). The lymph node architecture is preserved **(A)**, with reactive-appearing follicles **(B)**. **C,** Immunohistochemistry for BCL2 reveals occasional follicles containing strongly positive cells. The *inset* shows that some follicles are only partially involved. **D,** The BCL2-positive follicles tend to express CD10 more strongly than ordinary reactive follicles.

About 75% of cases express BCL2 protein (**Fig. 17-14H**)[109]; the frequency is highest (85% to 97%) in grade 1 to 2 cases and as low as 50% to 75% in grade 3 cases.[110,111] Expression of BCL2 protein is highly predictive of the presence of a *BCL2* translocation; however,

some cases of FL with *BCL2* rearrangement have mutations in the *BCL2* gene that affect detection of the protein by the commonly used antibody, resulting in a false-negative result (**Fig. 17-14I**).[112]

Neoplastic follicles contain many elements of the germinal-center microenvironment.[113] Nodular aggregates of FDCs outline the neoplastic follicles, demonstrated by antibodies to CD21 or CD23 (**Fig. 17-14J**). Expression of CD21 and CD23 is variable, and some FLs may express one and not the other; thus, staining for both may be necessary. In diffuse areas of FL, FDCs are absent (**Fig. 17-6I**); this may be useful in distinguishing diffuse FL from mantle cell and marginal zone lymphomas, in which large, irregular aggregates of FDCs are present, even in areas that appear diffuse on routine staining.[17,97] Neoplastic follicles also contain T follicular helper cells (positive for CD3, CD4, CD57, PD1, ICOS, and CXCL13), which are usually less numerous in neoplastic follicles than reactive follicles (**Fig. 17-14K**) and are randomly distributed; this contrasts with the crescentic arrangement at the junction with the mantle zone that characterizes reactive follicles.[114,115] Varying numbers of FoxP3-positive T-regulatory cells and CD68-positive histiocytes are present, and the number and/or distribution of tumor-infiltrating T-regulatory cells, PD1-positive T follicular helper cells, and CD68-positive macrophages have been reported to predict clinical prognosis in multiples studies,[116-126] although results are not uniform.[127]

Most cases of low-grade FL have a proliferation fraction with Ki-67 of less than 15% (**Fig. 17-14L**); however, rare cases have a high (>40%) proliferation fraction (**Fig. 17-14M and N**) and may behave more like grade 3 FL (see the section “Grading and Terminology”).[61]

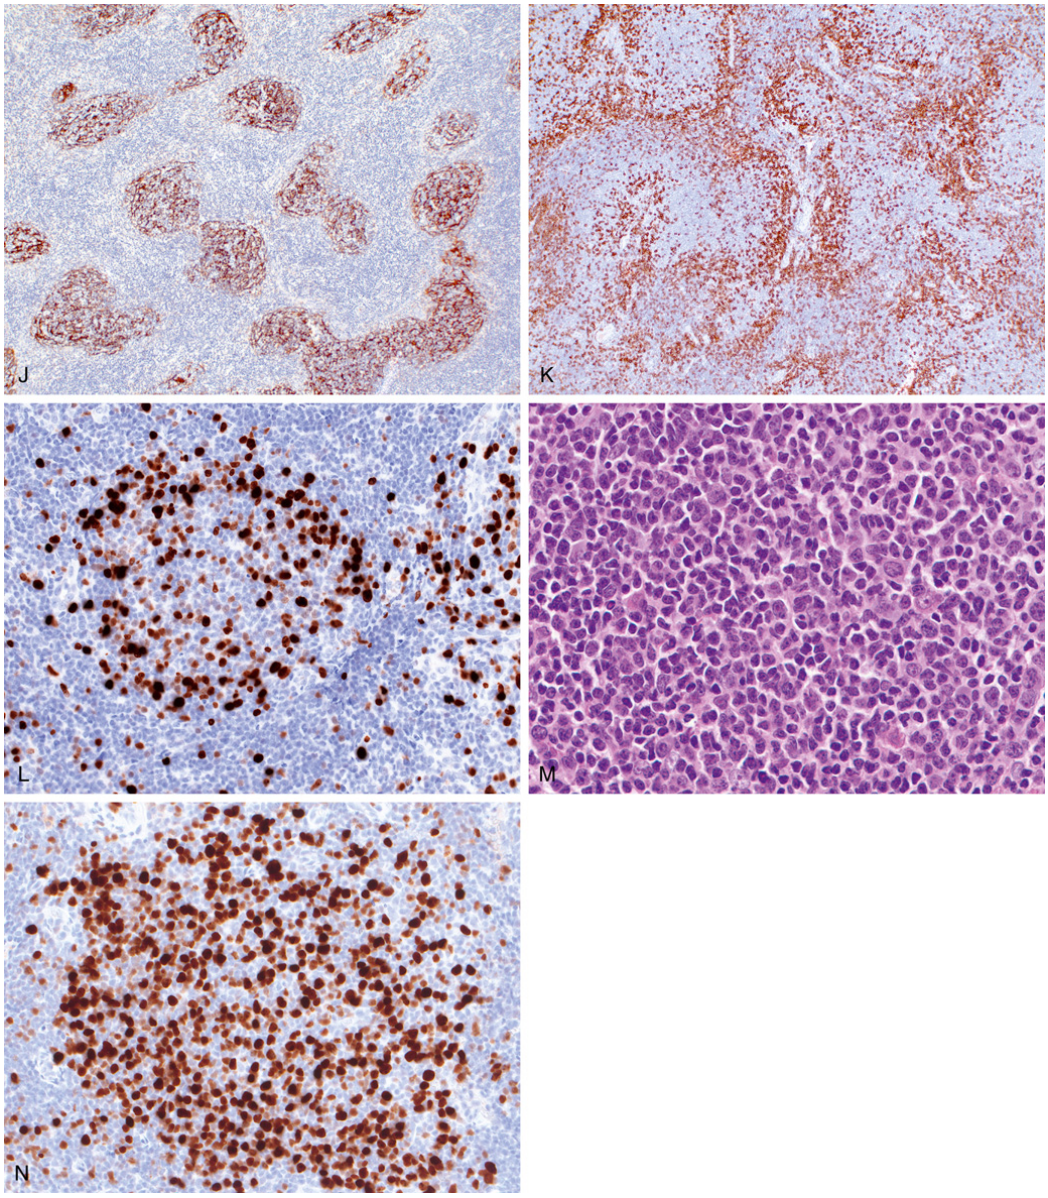

FIGURE 17-14 Immunohistochemistry of follicular lymphoma (FL) using immunoperoxidase stains in paraffin sections.A, A view at low magnification shows a lymphoproliferation with a nodular pattern. **B,** FL stained for CD20 shows that CD20-positive B cells are present both within and between follicles. Immunostains for immunoglobulin light

and heavy chains demonstrate faint interstitial staining for kappa **(C)** and monotypic expression of lambda light chain **(D)** and IgM **(E)** at the membrane of the lymphoma cells. **F,** FL immunostained for CD10 shows strongly positive cells largely confined to follicles.**G,** FL stained for BCL6 shows brightly positive cells essentially within the follicles, while a few interfollicular cells show fainter BCL6 staining. **H,** Immunoperoxidase stain for BCL2 in FL shows strong, uniform positivity within follicles. **a-d,** Immunoperoxidase stains show differential results with Dako and Epitomics antibcl2 antibodies in a case of grade 3A FL with *BCL2* rearrangement. The neoplastic follicles are negative for BCL2 with the Dako antibody (**a** and **c**), and positive for BCL2 when using the Epitomics antibody (**b** and **d**).**J,** Follicular dendritic cells associated with neoplastic follicles are highlighted by CD21. **K,** Immunostaining of FL for CD5 shows that neoplastic follicles contain few T cells, whereas numerous T cells are present in the interfollicular region. **L, The proliferation fraction with Ki67 is typically low.** Rare cases of low-grade FL **(M)** have a high proliferation fraction with Ki-67 (>40%) **(N)**.

Cytogenetic and Genetic Features

Antigen Receptor Genes

The IGH and Ig light-chain genes are clonally rearranged and, like normal germinal-center B cells, have somatic hypermutation in the variable regions.[128-131] In most cases studied, there is intraclonal variation in the pattern of somatic hypermutation, which has been interpreted to mean that the mutation process is ongoing in these cells—again, similar to normal germinal-center B cells.[132,133] Studies of the frequency of replacement to silent mutations in the framework and complementarity-determining regions have indicated a role for antigen selection.[128] As would be expected from normal germinal-center cells, IGH class switching occurs in approximately 40% of cases.[130] Some cases have evidence of both IgM and class-switched IgG clones in the same tumor; this finding has led to speculation that the class-switch mechanism, like the somatic mutation mechanism, remains active in lymphomas.[135] However, studies of sequential biopsies from the same patient indicate that the same clones persist over years, with some becoming dominant and others receding, but with no increase in the somatic mutation load, more consistent with clonal selection than with clonal evolution.[136,137] In addition, evaluation of microdissected cells from multiple follicles in a single case showed that multiple subclones were present within a single follicle, and a single clone may be found in multiple distant follicles.[138] These observations suggest that the hypermutation and class-switching mechanisms may be active very early in the development of lymphoma, leading to multiple subclones, but by the time the lymphoma is established, additional mutations and switching do not occur with any frequency.

In FLs that transform to LBCL, the Ig genes show identical *VDJ* rearrangements. In several reported cases, the transformed lymphoma involved a single clone, without intraclonal diversity.[135,139]

Cytogenetic Abnormalities

Virtually all FLs have cytogenetic abnormalities (**Table 17-5**).[140] Seventy-five percent to 90% have translocations involving the long arms of chromosomes 14 and 18 (t[14;18][q32;q21]), which places the *BCL2* gene on chromosome 18 under the influence of the IGH promoter on chromosome 14.[141,142] Rare cases have a t(2;18)(p12;q21), which places the *BCL2* gene with the light-chain gene on chromosome 2. In those with t(14;18) translocations, this is the sole abnormality in only 10% of cases; the remainder have additional breaks (a median of six in one study), most commonly involving chromosomes 1, 2, 4, 5, 13, and 17 or additions of X, 7, 12, or 18.[140,143] One study found that the presence of more than six chromosomal breaks was associated with a poor outcome; in addition, breaks at 6q23-26 or 17p conferred a poorer prognosis and a shorter time to transformation.[140,144] Another study found that the addition of X was associated with a worse outcome only in men.[143] The 17p abnormalities may reflect alterations in the *TP53* gene at 17p13, which have been associated with a poorer prognosis and with transformation in FL.[145,146] Abnormalities at 6q23-36 are found in 10% to 40% of B-cell lymphomas of all types and are the most common second abnormality in cases with t(14;18). Three distinct deletions have been described at 6q21, 6q23, and 6q25-27, suggesting the presence of three distinct tumor-suppressor genes.[147]

Deletions and other alterations of chromosome 9p, involving the *p15* and *p16* gene loci, have been reported in cases of FL that transform to DLBCL.[148,149] Array comparative genomic hybridization studies have demonstrated a large variety of chromosomal gains and losses, some of which are recurrent and have prognostic significance, including increased risk of transformation, particularly at 1p36 and 6q21.[150]

Table 17-5

* Associated with a poor prognosis.[140]

Recurrent Gene Rearrangements

BCL2

Analysis of the t(14;18)(q32;q21) breakpoint revealed a segment of DNA that was clonally rearranged in most FLs and comigrated with the rearranged Ig gene in Southern blots of tumor DNA.[151,152] The gene encoded by this segment was given the name *BCL2*. BCL2 protein is expressed by resting B and T cells but not by normal germinal-center cells or cortical thymocytes[153]—cell types in which negative selection and apoptosis represent important control mechanisms of immune system development—or by monocytoid B cells.[111] Overexpression of BCL2 protein confers a survival advantage on B cells in vitro by preventing apoptosis under conditions of growth factor deprivation.[154] Lymphocytes with *BCL2* rearrangement can be detected by polymerase chain reaction (PCR) in the tonsils and peripheral blood of many healthy individuals.[155,156] Thus, it appears that *BCL2* rearrangement by itself

is not enough to result in neoplastic transformation. Additional genetic abnormalities, or possibly a proliferative stimulus such as engaging the antigen receptor, are required for lymphoma development.

BCL6

The *BCL6* gene is a zinc finger transcriptional repressor gene that was cloned from the breakpoint of the 3q27 translocation found in a subset of DLBCLs.[157,158] It is normally expressed in germinal-center B cells[159,160] and in rare intrafollicular and interfollicular CD4-positive T cells; its presence is required for germinal-center formation.[161] The translocation, which involves a variety of partners, always involves the 5′ noncoding region of the *BCL6* gene, which is replaced by the promoter of the partner gene. It is presumed that these translocations prevent downregulation of *BCL6* and prevent the cell from progressing past the germinal-center stage, thus facilitating neoplastic transformation.[159] The *BCL6* gene undergoes mutations in the 5′ noncoding region in normal germinal-center B cells,[162-164] and a relationship between this process and Ig gene mutation has been suggested. Abnormalities of 3q27 or *BCL6* rearrangements are found in about 15% of FLs, whereas 5′ mutations of the *BCL6* gene are found in approximately 40%.[164]

MYC

Rare cases of FL studied at the time of diagnosis have both *BCL2* and *MYC* rearrangements (“double hit”); others acquire *MYC* rearrangement at the time of transformation to high-grade lymphoma.[165] Although concurrent *BCL2* and *MYC* rearrangements are typically associated with diffuse, high-grade B-cell lymphomas,

rare FLs have concurrent *MYC* and *BCL2* and/or *BCL6* rearrangements (double-hit or "triple-hit" FLs).[166,167] Patients with double-hit or triple-hit FLs are usually middle-aged or older adults, and there is a female preponderance, most with advanced clinical stage. Most cases are grade 2 or grade 3A. In one study, most cases showed >50% of cells expressing MYC protein, and the proliferation index was elevated in most cases (range, 1%–90%; median, 70%),[167] although MYC expression and elevation of proliferation index has not been uniformly as striking.[160] The immunophenotype is otherwise similar to that of conventional FL. In one study of 10 cases, 8 had concurrent *MYC* and *BCL2* rearrangements, one had *MYC* and *BCL6* rearrangements, and one had rearrangements of *MYC*, *BCL2* and *BCL6* (triple-hit FL).[167] Compared with FLs without *MYC* rearrangement, double-hit and triple-hit FLs affect similar patient populations, but they are more often grade 3 and may show more expression of MYC and have a higher proliferation index.[166-168] The behavior of double-hit/triple-hit FL is more indolent than that of high-grade double-hit or triple-hit B-cell lymphomas[168]; however, some investigators report more aggressive behavior than conventional low-grade FL and suggest that patients with double-hit FL may benefit from more aggressive therapy.[168]

Other cytogenetic abnormalities associated with distinctive features include deletions of 1p36 and *IRF4* translocation, discussed separately in this chapter (**Table 17-5**).

Mutational Landscape

Recurrent mutations in a number of epigenetic regulators are present in most cases of FL, demonstrating that FL is a disease of the

epigenome and of the genome. These mutations include recurrent mutations in histone methyltransferases *MLL2* and *EZH2* and histone acetylases *CREBBP, EP300,* and *MEF2B*.[169-171] *EZH2* is the best characterized. *EZH2* is a histone methyltransferase catalyzing trimethylation of lysine on histone H3 (H3K27me3). *EZH2* mutations lead to gain of function with enhanced trimethylation. They are relatively frequent, being identified in 27% of FLs in one published series.[172] Another series documented *EZH2* mutations in 22% of all FLs and in 28% of FLs with *BCL2* rearrangement.[173] Mutations in *MLL2* occur most frequently, with approximately 90% of cases having one or more mutations within this gene.

CREBBP is a histone acetyl transferase, mutations of which occur in 33% to 75% of FL cases.[174] Mutations in *CREBBP* may contribute to the pathogenesis of FL by decreasing acetylation of *BCL6,* leading to altered expression of *BCL6* target genes[174] MEF2B may also deregulate BCL6 transcriptional activity.[175]

Other genes with recurrent mutations in FL include histone linker genes histone *H1 B, C, D,* and *E*; transcription factors *OCT2* and *STAT6; TNFRSF14;* and *IRF8* and *ARIDA*.[176,177] Mutations in *NOTCH1* and *NOTCH2* (**Table 17-5**) are occasionally present.

Gene Expression Profiles

The gene expression profile of FL by DNA microarray analysis shows many similarities to normal germinal-center cells.[178,179] Genes upregulated in FL include *BCL2;* genes involved in cell cycle regulation, including *CDK10, p21CIP1,* and *p16INK4A;* transcription factors involved in B-cell differentiation such as *PAX5;* and some genes involved in cell-cell interactions such as *IL4R*. Others are

downregulated, including *MRP8* and *MRP14,* which are involved in the inhibition of cell migration, and CD40, which is important in interactions with T cells.[178,179] Genes associated with the germinal-center microenvironment (T cells, dendritic cells, macrophages) are also expressed in FL, and differential expression of these genes is associated with clinical aggressiveness.[116-125]

Postulated Normal Counterpart and Pathogenesis

FL is a tumor of germinal-center B cells in which centrocytes fail to undergo apoptosis because they have a chromosomal rearrangement, t(14;18), that prevents the normal switching off of the antiapoptosis gene *BCL2*.[109,153] They retain their ability to interact with T cells and FDCs to form neoplastic follicles. It is likely that cases negative for *BCL2* rearrangement have alternative mechanisms for cell survival, such as decreased expression of proapoptotic proteins.[180]

Etiology

The cause of FL is unknown. Some case-control studies have found slightly higher risk of FL among individuals exposed to pesticides or hair dye and in meatpackers and smokers, but these risks are small and inconsistent.[5] There are no known links with suspected lymphoma-associated viruses such as human herpesvirus 8 or hepatitis C virus or with immune deficiency states. Rare FLs, usually grade 3, harbor Epstein-Barr virus, which may play a role in lymphomagenesis and/or disease progression.[181,182]

Many, if not most, healthy adults have memory B cells with rearranged *BCL2* genes, detectable by PCR or FISH in peripheral blood, tonsils, bone marrow, or lymph nodes.[156,183] The frequency of these translocations does not appear to vary across populations with differing incidences of FL. However, several studies suggest an increase in such cells with age, and one with exposure to cigarette smoke.[9] It has been postulated that a second genetic “hit” or even simple exposure to antigen in a cell with a *BCL2* translocation could

result in the development of lymphoma, because once it begins proliferating in response to antigen, it does not respond to the usual stimuli for apoptosis.

FL cells have somatic hypermutations in the variable regions of their Ig genes, and there is intraclonal variation within most tumors, similar to normal germinal-center B cells. These features suggest that antigen may be important in either the pathogenesis or the persistence of the neoplastic clone.[133]

As previously noted, numerous genes are mutated in FL. In addition, there is prominent intratumoral clonal diversity with respect to mutations affecting some genes. Dominant clones of FL and later transformation events arise by divergent evolution from a common mutated precursor through acquisition of distinct genetic events.[184] Those mutations that are nearly uniformly present likely represent early events, and those present only in a subset of tumor subclones are likely acquired later.[175] The *BCL2* translocation can be considered a founder mutation, enabling cells to live long enough to acquire additional mutations, but it is not sufficient by itself to result in overt lymphoma.[175] The clone may then acquire secondary, driver mutations, such as mutations of *CREBBP* and *EZH2,* which, when present, are found in a high proportion of clonal cells. Over time, some clonal cells may acquire tertiary *accelerator mutations* of genes such as *MLL2* or *TNFRSF14,* further promoting growth of the neoplastic clone.[175]

Clinical Course

Natural History

FL is usually a disseminated, indolent neoplasm; the median survival of patients treated palliatively is more than 10 years.[185] With current therapies, including the use of monoclonal antibodies in combination with chemotherapy, the median OS is 15 to 20 years. The natural history of FL is characterized by a protracted relapse-remitting course, with eventual treatment refractoriness. This is considered incurable, but there is significant clinical heterogeneity among patients. Of patients who require chemotherapy, 10% to 20% show progression of disease within 24 months of immunochemotherapy (POD24), an event associated with poor outcomes, with 50% of patients alive after 5 years. Histologic transformation of FL to DLBCL occurs at a risk of 1% to 3% per year,[186-189] with a median time to transformation of 2.5 to 4.1 years, also associated with poor outcomes.

Treatment

There are no clearly agreed upon treatment algorithms for patients with FL. As there is no data demonstrating benefit of treating patients early in their course without problematic symptoms or suspicion of high-risk disease, a “watch and wait” approach is often taken for advanced stage low-grade FL. Indications for therapy include symptomatic disease, bulky lymphadenopathy, marrow compromise and rapid progression of disease. Treatment for grade 1 to 2 FL is generally directed at relief of symptoms rather than cure. Patients with localized disease (stage I) may have prolonged disease-free survival after excision or local radiation therapy.[190,191] Patients with more typical advanced-stage disease may be followed clinically until symptoms require treatment.[185] The standard of care for the

first-line treatment of patients with advanced stage FL is chemotherapy with rituximab (an anti-CD20 monoclonal antibody). Rituximab is often used in combination with CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), CVP (cyclophosphamide, vincristine, and prednisone), fludarabine and cyclophosphamide, or bendamustine. The use of rituximab is more effective than chemotherapy alone and has contributed to better outcomes.[192-196] Of these chemotherapeutic regimens, studies have provided some evidence of increased progression-free survival and fewer toxic effects with bendamustine plus rituximab (BR), suggesting BR may be considered the preferred first-line treatment.[197,198] High-dose therapies with autologous or allogeneic stem-cell rescue are often used after the first or subsequent chemo-sensitive relapse; some studies show evidence of improved survival.[199,200] Chimeric antigen receptor (CAR) T cells are now licensed for treatment of multiply relapsed FL.

Prognosis and Predictive Factors

Clinical Factors

Though it is clear that progression of disease by 24 months (POD24) is associated with poor outcomes, there is a need for prognostic markers that can be applied at the time of diagnosis to identify patients who have a good or poor prognosis. There are no clinical predictors or biomarkers yet available to predict who will experience POD24 prior to therapy initiation. Over the years, several prognostic scoring systems have been developed to stratify those patients who will have a good or bad prognosis, including the follicular lymphoma international prognostic index (FLIPI)[201] (based on age, stage,

number of involved nodal sites, hemoglobin, and lactate dehydrogenase [LDH] level) and FLIPI2[202] (incorporating β_2-microglobulin, the diameter of the largest lymph node, bone marrow involvement, and hemoglobin level). The FLIPI and FLIPI2 each define three prognostic risk groups, with the latter system discriminating low-risk patients with 96% 5-year OS, intermediate-risk patients with 80% 5-year OS, and high-risk patients with 50% OS. An m7-FLIPI score was also created that incorporates clinical features and mutational status of seven genes *(EZH2, ARID1A, MEF2B, EP300, FOXO1, CREBBP, CARD11)*, which was validated on patients receiving RCHOP or CVP chemotherapy.[203] Histologic transformation is associated with poor prognosis. Biomarkers have yet to be identified that can be used to detect patients at increased risk for histologic transformation.[5,22]

Histologic Grade

The prognostic value of grading FL has been debated for years. Traditionally, the clinical aggressiveness of FL has been thought to increase with the number of centroblasts. For decades, cell counting methods based on the original "Mann and Berard" method have been used to determine FL grade.[52,54] However, the prognostic significance of FL grading has been a matter of debate and considered in each of the past editions of WHO classification. In the 2017 WHO classification (revised 4th edition or WHO-HAEM4R), grade 1 and grade 2 FL were combined into a low-grade FL category (e.g., grade 1 to 2 FL) based on the realization that there is no prognostic significance between grade 1 and grade 2. Several studies conducted in the pre-rituximab era of the 1970s to the 1990s

suggested a significantly more aggressive clinical course for grade 3 FL cases.[56,59,204,205] However, more recent studies focusing on genetic features and clinical behavior of cases using this grading system have provided some evidence that grade 3A FL may be more indolent and more closely related to low-grade FL.[206-208] In addition, several clinical trials performed for new targeted therapies have shown no differences in outcome between grade 1 to 2 and grade 3A FL.[209-214] Of all patients receiving first-line therapy, approximately 20% progress within 24 months (POD24 group) with a 5-year survival of 50%, in contrast to the non-POD24 group with a 5-year OS of 90%. POD24 status has shown no correlation with histologic grade.[211,215] Of note, there has been one paper studying genetic alterations predictive of transformation that showed 40% of grade 3A cases displayed subsequent high-grade transformation versus only 10% of FL grade 1 to 2 cases,[211] suggesting grade 3A FL cases are enriched for more aggressive cases. Several studies have shown the frequent association of FL grade 3B with areas of DLBCL and that FL grade 3B is genetically and behaviorally more related to DLBCL.[46,58,216-218]

The 2022 ICC classification continues to recommend morphologic grading of FL (grades 1 to 2, 3A, and 3B) as previously described. In contrast, because of the continued debate over FL grading, the proposal for the WHO 5th edition consensus removed the requirement to grade FL and proposed a new system of subclassification using four subgroups: (1) cFL, having at least a partial follicular pattern and composed of both centrocytes and centroblasts. This subgroup includes grade 1 to 2 and 3A FL as defined by the ICC; (2) FLBCL, having a purely follicular pattern and

composed of sheets of centroblasts. These cases are analogous to grade 3B FL as defined by ICC; (3) uFL, having an at least partially follicular pattern and composed of medium-sized cells with blastoid/immature chromatin or large cells with cleaved/irregular nuclei (e.g., large centrocytes), and (4) dFL, having an entirely diffuse pattern (no follicles) and a mixture of centrocytes and centroblasts. This is analogous to diffuse FL as defined by ICC and includes a large subset of the cases with absence of *BCL2* gene rearrangement, microfollicles, *STAT6* mutations, 1p36 deletions, and frequent inguinal lymph node involvement, designated "BCL2-R-negative, CD23+ FL" by the ICC. Because of these differences (summarized in **Table 17-2**, Synonyms and Related Terms), for routine clinical diagnosis, it is recommended to provide both the ICC and proposed WHO 5th edition nomenclature for clarity.

Diffuse Areas

The effect of diffuse areas on survival in patients with grade 1 to 2 FL is controversial. Some studies have found that the presence of even very large diffuse areas in FL grade 1 or 2 (small, cleaved cell type or mixed small and large cell type) did not significantly alter the prognosis[219]; others have suggested that the proportion of follicular pattern does affect survival.[220,221] Diffuse areas with sufficient large cells for a diagnosis of DLBCL are more common in grade 3 FL than in grade 1 and grade 2 cases. Most observers believe this finding is clinically significant,[56,58,219] conferring a poorer prognosis, although results have not been uniform.[53,222]

Histologic Transformation

Progression to DLBCL or high-grade B-cell lymphoma (not otherwise specified [NOS] or with concurrent rearrangements of *MYC* and *BCL2* +/− *BCL6*) is usually associated with a rapidly progressive clinical course and may result in death from a tumor that is refractory to treatment (**Fig. 17-15**).[185,186,223-226] Of note, rare cases of TdT-positive pre-B-lymphoblastic leukemias/lymphomas (pB-ALL/LBL) have *MYC* and *BCL2* dual translocations and are seen particularly in children and young adults.[227,228] These can be challenging to distinguish from high-grade B-cell lymphomas with *BCL2* and *MYC* gene rearrangements, but flow cytometric characterization to distinguish a precursor versus mature B-cell state and molecular studies (*NRAS/KRAS* mutations in preB-ALL/LBL) may be helpful.[228]

Differential Diagnosis

See **Box 17-2**.

Follicular Hyperplasia

Reactive follicular hyperplasia is the major differential diagnosis in cases of FL. In the vast majority of cases, typical architectural and cytologic features permit the diagnosis of FL based on morphologic criteria alone.[229,230] In difficult cases, immunophenotyping and, occasionally, molecular genetic studies can be helpful in establishing a diagnosis.

Morphologic Criteria

Pattern

Effacement of the normal architecture by closely packed, relatively uniform follicles that lack a mantle zone and extend outside the nodal capsule is characteristic of FL (**Table 17-6**). Close packing of follicles, even focally—particularly if the follicles are small and uniform—is highly suggestive of lymphoma. If the follicles are widely spaced, the interfollicular region should be examined at high magnification for the presence of centrocytes. Although transformed cells (immunoblasts and occasionally centroblasts) can be seen in the interfollicular regions of reactive nodes, centrocytes are virtually never found outside germinal centers in normal lymph nodes. Extension of follicles outside the capsule in association with concentric bands of sclerosis is a helpful feature supporting FL (**Fig. 17-1A**). Capsular fibrosis often occurs in lymphadenitis, with small lymphocytes and plasma cells present in perinodal fat, but follicles with germinal centers are rarely seen outside the capsule. Sclerosis within the lymph node, particularly in diffuse areas, is also suggestive of lymphoma; areas of sclerosis should be scrutinized at high magnification for the presence of centrocytes. Finally, transmural invasion of the walls of small or medium-sized veins by centrocytes, either within the node or in perinodal tissue, is highly suggestive of lymphoma (**Fig. 17-3B and C**).

Cytology

Cases that are difficult to diagnose are typically grade 3, in which the increased number of centroblasts more closely approximates the normal germinal center. In these cases, the absence of phagocytic tingible body macrophages, relatively low mitotic rate, lack of polarization, crowding of follicles, and lack of a mantle zone are

helpful features. In some FLs, the centroblasts or large centrocytes have a cytologically atypical appearance, with hyperchromatic or abnormally shaped nuclei. The cytology of the interfollicular, extranodal, and diffuse areas in these cases can be essential in establishing the diagnosis.

Immunophenotyping

In distinguishing benign from malignant lymphoid infiltrates, the most reliable criterion is Ig light-chain restriction, which is best evaluated by flow cytometry. Evidence of light-chain restriction (kappa or lambda) is usually diagnostic of lymphoma. However, clonal B cells have been reported within some follicles in cases of apparent reactive hyperplasia,[231] and clonal CD10-positive B cells may be detected by flow cytometry in cases of florid follicular hyperplasia in children.[96] Thus, these results must be analyzed in the context of the morphologic appearance.

Immunohistochemical staining for BCL2 protein is the most useful technique for distinguishing FL from follicular hyperplasia on paraffin sections. Sections must be examined together with sections stained for CD20 and CD3, because numerous BCL2-positive T cells may be present in both reactive and neoplastic follicles; staining of these cells should not be misinterpreted as BCL2 expression by neoplastic cells. In many cases, the neoplastic follicle center cells express BCL2 more strongly than do the surrounding mantle zone or interfollicular cells; in some cases, however, staining of FL cells may be faint and restricted to a subset of centrocytes. BCL2 staining should be interpreted together with BCL6, CD10, or FDC staining, because expression of BCL2 by non–germinal center B cells is not indicative of lymphoma. Unfortunately, BCL2 positivity is less common in grade 3 FL, making it difficult to differentiate it from reactive hyperplasia, so the absence of BCL2 does not exclude lymphoma.[110] It is important to remember that some BCL2-negative cases have alterations related to somatic hypermutation involving the BCL2 epitope that can prevent standard BCL2 antibodies form

binding, resulting in a falsely negative BCL2 staining. In these cases, alternative BCL2 antibodies may be used to show BCL2 expression.

Box 17-2 Differential Diagnosis of Follicular Lymphoma

- Follicular hyperplasia

    - Small lymphocytic lymphoma
    - Mantle cell lymphoma
    - Marginal zone lymphoma
- Hodgkin lymphoma
    - Nodular lymphocyte-predominant Hodgkin lymphoma
    - Nodular sclerosis classic Hodgkin lymphoma

Table 17-6

Histologic Features Useful in Distinguishing Follicular Lymphoma (FL) From Follicular Hyperplasia

Characteristic	Specificity for FL	Frequency in FL
Centrocytes predominate in follicles	Diagnostic	High
Centrocytes present between follicles	Diagnostic	High
Vascular invasion by centrocytes	Diagnostic	Moderate
Close packing of follicles	Highly suggestive	High
Diffuse areas or sclerosis	Highly suggestive	Moderate
Follicles extend beyond nodal capsule	Highly suggestive	High
Mantle zone absent	Suggestive	High
Starry-sky cells absent in follicles	Suggestive	High
Mantle zone present	Not helpful	Low
Some reactive follicles	Not helpful	Low

Characteristic	Specificity for FL	Frequency in FL
present		
Size, shape, uniformity of follicles	Not helpful	—
"Cracking" artifact or compression of reticulin	Not helpful	—

Expression of CD10 or BCL6 by follicles is not a criterion for malignancy, because it is also expressed by normal germinal-center cells.[97] CD10 is typically expressed more strongly in neoplastic than reactive germinal centers, and BCL6 may be expressed by fewer cells in FL than in follicular hyperplasia. Detection of CD10-positive or BCL6-positive cells in the interfollicular region is suggestive of FL. However, rare normal interfollicular cells may be BCL6 positive, and interfollicular neoplastic cells may lack CD10 or express it more weakly than those within the follicles.[32,97] Assessment of the proliferation fraction using Ki-67 may be helpful, because in reactive follicles, the vast majority of the cells are in cycle, whereas even in grade 3 FL, the proliferation fraction is rarely greater than 60%.

Molecular Genetic Analysis

PCR analysis for clonal Ig rearrangement can be more sensitive for detecting small clonal populations than conventional immunophenotyping and may also prove clonality in Ig-negative or BCL2 protein–negative tumors.[142] This assay may be subject to false negative results in some cases, as extensive somatic hypermutation may result in poor binding of PCR primers.[232] FISH analysis for

translocation of *BCL2* or *BCL6* can also be helpful in establishing a diagnosis of FL in difficult cases.[233]

Other Small B-Cell Lymphomas

Other lymphomas with a nodular or follicular pattern may resemble FL. These include mantle cell lymphoma, marginal zone lymphoma, occasionally small lymphocytic lymphoma, and rarely, Hodgkin lymphoma.

Morphologic Features

The morphologic features of small B-cell lymphomas are summarized in **Table 17-7**. Chronic lymphocytic leukemia–small lymphocytic lymphoma (CLL/SLL) typically has a pseudofollicular pattern in lymph nodes related to the presence of proliferation centers; this can be mistaken for a true follicular pattern, resulting in confusion with FL. In general, proliferation centers are poorly demarcated from the surrounding infiltrate, so they seem to "disappear" at progressively higher magnifications. They are slightly paler than surrounding small dark lymphocytes, imparting a "cloudy sky" pattern. They contain cells with predominantly round nuclei and show a subtle gradation from small lymphocytes to prolymphocytes to paraimmunoblasts, in contrast to the sharp dichotomy between centrocytes and centroblasts in FL. Sclerosis and extranodal extension are uncommon in CLL/SLL.

Cases of mantle cell lymphoma may have a vaguely nodular or, rarely, a true follicular pattern. In most cases, the follicular pattern is only focal, with large diffuse areas. In contrast to FL, which always contains a mixture of neoplastic centroblasts and centrocytes, mantle cell lymphoma typically contains a monotonous population of small

cells that resemble centrocytes, with virtually no blast cells. Occasional centroblasts can be seen in areas of partially overrun follicles. In many cases, foci of preserved germinal centers surrounded by a mantle zone of atypical cells can be found; this appearance would be unusual in FL. Many cases of mantle cell lymphoma contain single epithelioid histiocytes. Mantle cell lymphoma often has a higher mitotic rate than FL. The character of the blood vessels may also provide a clue to the diagnosis. In mantle cell lymphoma, the small vessels usually are not high endothelial venules; they have flat endothelial cells and often have eosinophilic sclerosis of their walls. In contrast, in diffuse areas of FL, the small vessels usually are high endothelial venules and do not show prominent sclerosis. Compartmentalizing fibrosis, which is commonly seen at least focally in diffuse FL, is rare in mantle cell lymphoma. Finally, diffuse areas of FL frequently contain large numbers of small, reactive T lymphocytes, whereas mantle cell lymphoma may show frequent scattered epithelioid histiocytes and fewer other reactive cells.

Marginal zone lymphomas may have a partially follicular pattern owing to the presence of follicles that have been “colonized” by neoplastic marginal zone cells. Typically, these follicles are widely spaced on a background of interfollicular marginal zone cells, but occasionally they may be numerous and mimic FL. In addition, FL may have marginal zone differentiation, mimicking marginal zone lymphoma (**Fig. 17-2**). Marginal zone B cells have centrocyte-like nuclei but more abundant cytoplasm; however, occasional FLs may have cells with relatively abundant cytoplasm. Marginal zone lymphoma also enters the differential diagnosis of diffuse FL,

because both contain a mixture of small cells with irregular nuclei and large centroblasts or immunoblasts. Problems can also arise when biopsy specimens are small and a mixed population of centrocyte-like and centroblast-like cells is present without an obvious pattern. Features favoring marginal zone lymphoma include a predominant interfollicular infiltrate, irregular follicles, foci of reactive-appearing follicles, abundant cytoplasm, and plasmacytoid differentiation. Features favoring FL include monomorphism; round, uniform, and closely packed follicles; sclerosis; and vascular invasion.

Immunophenotype

The immunophenotypic and genetic features of small B-cell lymphomas are summarized in **Table 17-8**. Mantle cell lymphoma and CLL/SLL characteristically express IgM, IgD, CD5, and CD43; most cases are CD10 negative. In contrast, FL is usually IgD negative, IgG positive, or IgM positive and CD5 negative; 50% to 80% of cases are CD10 positive.[101] With antibodies to FDCs, follicular areas in FL are highlighted by concentric aggregates of FDCs, whereas diffuse areas show few, if any, FDCs; in contrast, both mantle cell lymphomas and many marginal zone lymphomas contain large, irregular FDC aggregates, even in areas that are diffuse on routine sections.[97,234] Staining for BCL2 may highlight residual negative reactive follicles in mantle cell lymphoma and marginal zone lymphoma, whereas follicle centers are typically positive in FL. BCL2 staining of the extrafollicular neoplastic cells is not helpful in the differential diagnosis of small B-cell lymphomas because all can be positive. Finally, staining for cyclin D1 and/or SOX11 is positive in

almost all mantle cell lymphomas but is negative in FL.[235] This is particularly useful in the rare cases of CD5-negative mantle cell lymphoma.[236]

* In occasional cases, there may be a few cyclin D1-positive cells in proliferation centers.

Immunophenotyping can be useful in the differential diagnosis between FL and marginal zone lymphoma with follicular colonization, but it requires careful interpretation because of the complex architecture of these neoplasms. The most useful antigens are CD10, BCL6, and BCL2; all must be assessed with respect to CD21-positive or CD23-positive FDC aggregates, which define the follicular areas. In FL, most of the cells within the FDC aggregates should be BCL2 positive, CD10 positive, and BCL6 positive, whereas in marginal zone lymphoma they are heterogeneous. Noncolonized follicles are BCL2 negative, CD10 positive, and BCL6 positive; partially colonized follicles have an admixture of BCL2-positive, CD10-negative, and BCL6-negative neoplastic cells and BCL2-

negative, CD10-positive, and BCL6-positive reactive follicle center cells; and completely colonized follicles are typically BCL2 positive, CD10 negative, and BCL6 negative. Expression of CD10 or BCL6 by extrafollicular B cells (away from FDC aggregates) supports follicle center lymphoma, whereas CD10-negative, BCL6-negative extrafollicular B cells favor marginal zone lymphoma.[99,234,237] MUM1/IRF4 is helpful if positive, because most FLs are MUM1/IRF4 negative and some marginal zone lymphomas are positive. The presence of light-chain–restricted plasma cells and aberrant expression of CD43 also favor a diagnosis of marginal zone lymphoma.

Genetic Analysis

The *BCL2* rearrangement characteristic of FL is rare or absent in mantle cell, small lymphocytic, and marginal zone lymphoma. The *CCND1* gene rearrangement is detectable in most cases by FISH and by PCR in about 40% of mantle cell lymphomas but not in FL (**Table 17-8**).

Pearls and Pitfalls

- FL is a distinctive tumor that reproduces most of the morphologic, immunophenotypic, and genetic features of the lymphoid germinal center. Clinically, FL is usually an indolent lymphoma with a long median survival.
- The majority of FL cases are characterized by follicular architecture, predominantly centrocytic composition and

BCL2 expression by germinal center B cells, secondary to *BCL2* gene rearrangements resulting activation of a gene, *BCL2 ,* that confers a survival advantage on nonproliferating neoplastic cells.

- Several FL variants have been described that present as localized nodal (pediatric-type FL) or extranodal disease, lack *BCL2* gene rearrangements, and have generally excellent prognosis.
- BCL2-R-negative and CD23-positive follicle center lymphoma is a unique variant of FL characterized by the absence of *BCL2* gene rearrangements, often localized lymphadenopathy, most commonly in the inguinal area, and often growing in an architecturally diffuse pattern, though some cases can show follicular architecture. These cases are usually positive for CD23 and have recurrent deletions of 1p36 and *STAT6* or *SOCS1* mutations.

In classifying non-Hodgkin lymphomas, considerable attention has been paid to architectural, cytologic, and functional similarities among the various lymphomas and normal lymphoid tissue, exemplified by the peripheral lymph node. However, studies of extranodal lymphomas, particularly gastrointestinal lymphomas (accounting for the majority), suggest that in many cases their clinicopathologic features are related not to lymph nodes but to the

structure and function of mucosa-associated lymphoid tissue (MALT).[1,2]

The anatomic distribution and structure of lymph nodes are adapted to deal with antigens carried to the node in afferent lymphatics, which drain sites at various distances from the node. Permeable mucosal sites, such as the gastrointestinal tract, are particularly vulnerable to pathogens and antigens because they are in direct contact with the external environment, and specialized lymphoid tissue—MALT—has evolved to protect them. MALT includes gut-associated lymphoid tissue, nasopharyngeal lymphoid tissue (tonsils), and other less well-characterized aggregates of lymphoid tissue related to other mucosae. Gut-associated lymphoid tissue serves as the paradigm for MALT (**Fig. 18-1**).

Definition

Extranodal marginal zone lymphoma (MALT lymphoma) is an extranodal lymphoma composed of morphologically heterogeneous small B cells, including marginal zone (centrocyte-like) cells, cells resembling monocytoid cells, small lymphocytes, and scattered immunoblast and centroblast-like cells. There is plasma cell differentiation in a proportion of cases. The infiltrate expands the marginal zone of reactive B-cell follicles and extends into the interfollicular region. In epithelial tissues, the neoplastic cells typically infiltrate the epithelium, forming lymphoepithelial lesions.[3,4]

MALT lymphomas arise in a wide variety of extranodal sites (**Boxes 18-1** and **18-2**), but curiously, most of these are not sites where MALT is normally present, such as the terminal ileum or the

tonsils. One could question whether the term *MALT* is appropriate for lymphomas, such as those of the orbit, that do not arise in mucosal or epithelial tissues; however, their close association with mucosal tissue, together with their histology, immunophenotype, and genetic and clinical properties, tend to support their classification as MALT lymphomas. In the revised 4th edition WHO classification, cases arising at all anatomic sites were classified under the term extranodal marginal zone lymphoma. In the 2022 International Consensus Classification (ICC), primary cutaneous cases are designated as primary cutaneous marginal zone lymphoproliferative disorders in recognition of their very indolent behavior (see **Chapter 19**). They are also separately designated in the proposed WHO 5th ed.

WHO proposed 5th ed. (noncutaneous sites): Extranodal marginal zone lymphoma

Epidemiology

MALT lymphomas account for 5% to 8% of all B-cell lymphomas and at least 50% of primary gastric lymphomas.[5-8] The incidence of MALT lymphoma has increased over the past three decades, reflecting at least in part improved pathologic diagnosis during this time period.[6,9-16] Although MALT lymphoma is described in almost all extranodal tissues, the stomach is the most common site (30% of cases), followed by ocular adnexa (12%), skin (10%), lung (9%), salivary gland (7%), other gastrointestinal sites (7%), breast (3%), and thyroid (2%).[12,16] Several studies have reported a decreasing incidence of gastric MALT lymphomas over time, most likely

reflecting a decreasing prevalence of *Helicobacter pylori* infection and widespread early treatment of patients with peptic disease symptoms.[12,17,18] Most MALT lymphomas occur in adults, with a median age in the seventh decade of life.[12,17] Overall, males and females show a largely similar incidence, although gender disparities are found at specific anatomic sites.[12,16] For example, there is a female predominance in salivary gland, thyroid, and breast MALT lymphomas, whereas primary cutaneous marginal zone lymphoproliferative disorder shows a male predominance.[12,16] Although a higher incidence of gastric MALT lymphoma was previously noted in northeastern Italy, probably related to a high prevalence of *H. pylori*–associated gastritis in that region, an incidence on par with other Western countries has been observed more recently.[12,17-19] Immunoproliferative small intestinal disease (IPSID), previously also known as α-heavy chain disease or Mediterranean lymphoma, is a special subtype of MALT lymphoma that most commonly occurs in developing countries, and is linked to factors associated with low socioeconomic status, including poor hygiene, malnutrition, and frequent intestinal infections.[20-22]

Box 18-1 Localization of MALT Lymphoma

- Gastrointestinal tract
  - Stomach
  - Intestine (including immunoproliferative small intestinal disease)
- Salivary glands

- Respiratory tract
    - Lung, pharynx, trachea
- Ocular adnexa
    - Conjunctiva, lacrimal gland, orbit
- Skin
- Thyroid gland
- Liver
- Genitourinary tract
    - Bladder, prostate gland, kidney
- Breast
- Thymus
- Rare sites

Box 18-2 Major Diagnostic Features

- Tumors arise at extranodal locations, usually sites of acquired MALT.
- The neoplastic cells include variable numbers of small lymphocytes, marginal zone–like cells, and scattered large cells; a subset show plasmacytic differentiation.
- Neoplastic cells surround and colonize germinal centers and lymphoepithelial lesions are common at many, but not all, anatomic sites.
- The B cells typically lack expression of CD5, CD10, and CD23. A subset shows co-expression of CD43.

- Translocations including *BIRC3*::*MALT1, IGH*::*MALT1,* and *IGH*::*BCL10* occur in a minority of cases.

Etiology

MALT lymphomas only rarely arise from native MALT; they usually arise from MALT that has been acquired as a result of a chronic inflammatory disorder at sites normally devoid of MALT, such as the stomach, salivary gland, lung, thyroid gland, and ocular adnexa. MALT lymphomas of the salivary gland and thyroid gland, organs normally containing no lymphoid tissue, are preceded by lymphoepithelial (myoepithelial) sialadenitis (LESA) or lymphocytic thyroiditis,[23-25] usually associated with Sjögren syndrome and Hashimoto's disease, respectively. Histologic and immunohistochemical studies of the heavy lymphoid infiltrate that characterizes these two conditions have shown a remarkable resemblance to Peyer's patches.[23-25] This is most graphically illustrated with reference to LESA. In this condition, lymphoid tissue accumulates around dilated salivary gland ducts and forms, in effect, small Peyer's patches, complete with a germinal center, mantle, small marginal zone, and, significantly, lymphoepithelium comprising collections of intraepithelial B cells (**Fig. 18-2**).[23,25] This lymphoid tissue, known as acquired MALT, is also a feature of Hashimoto's disease, and it has been identified in fetal and neonatal lung from infants with pulmonary infections of an undetermined nature.[26] It is also seen in a condition termed *follicular bronchiolitis*, which is associated with various autoimmune disorders, including Sjögren syndrome, and immunodeficiency.[27,28] It is worth emphasizing that native MALT, in the form of bronchus-

associated lymphoid tissue, is not present in the normal lung. Likewise, lymphoid tissue is not present in the normal stomach, the most common site of MALT lymphoma; here too, MALT is commonly acquired, most frequently subsequent to infection with *H. pylori*.[29] Other infectious organisms have been implicated as etiologic agents of MALT lymphoma at other sites.

Certain common factors relating to the acquisition of MALT may be relevant to the development of lymphoma at these sites. Chronic antigenic stimulation, related to the underlying infection or autoimmune disorder, plays an important role in the underlying disease. MALT accumulates in relation to columnar epithelium and appears to receive antigenic stimuli either from the epithelium itself or, like physiologic MALT, from antigens that enter the lymphoid tissue across the epithelium, rather than from antigens carried in afferent lymphatics.[20,30] The functional characteristics of this acquired MALT and the degree to which it resembles normal MALT remains unclear. Studies of *H. pylori*–associated gastric MALT lymphoma offer insights into the mechanisms that underlie the transition from reactive to neoplastic marginal zone B cells. It is thought that the immune response elicited by *H. pylori* initially supports expansion of polyclonal B cells that have the ability to recognize cross-reactive autoantigens present in the gastric mucosa via their B-cell receptor.[31,32] Several studies have shown that MALT lymphomas from different anatomic sites show biased usage of IGHV genes, lending support to the concept that the B-cell expansion is driven by autoantigens or alloantigens specific to the tissue microenvironment in which the lymphoma develops.[32-35] Persistent activation by autoantigens, *H. pylori*–specific T cells, and potentially

direct stimulation by *H. pylori* cytotoxin-associated gene A (CagA) protein encourage polyclonal B-cell expansion and selection, which eventually results in the emergence of an antigen-dependent B-cell clone.[31,32,36,37] Acquisition of additional genetic abnormalities promoting constitutive activation of pathways intrinsic to the chronic inflammatory response, particularly the NF-κB pathway, allows the B-cell clone to progress toward *H. pylori*–independent proliferation and malignant transformation.[30-32]

Infectious Agents

Helicobacter pylori and Gastric MALT Lymphoma

Several lines of evidence suggest that gastric MALT lymphoma arises from MALT acquired as a consequence of *H. pylori* infection. The first study in which this association was examined showed that the organism was present in more than 90% of cases.[38] A subsequent case-control study showed an association between previous *H. pylori* infection and the development of primary gastric lymphoma.[39] More compelling evidence confirming the role of *H. pylori* in the pathogenesis of gastric lymphoma has been obtained from studies that detected the neoplastic B-cell clone in the chronic gastritis that preceded the lymphoma,[40] as well as from a series of in vitro studies showing that lymphoma growth could be stimulated in culture by *H. pylori* strain-specific T cells when crude lymphoma cultures were exposed to the organism.[41] Studies have also shown that *H. pylori* CagA protein can enter B cells, potentially directly promoting cell proliferation and the upregulation of antiapoptotic molecules BCL2 and BCXL.[31,36,37] Finally, after the initial study by Wotherspoon and colleagues,[42] several groups have confirmed that eradication of *H. pylori* with antibiotics results in regression of gastric MALT lymphoma in 75% of cases. More recent studies have shown that in the era of widespread use of antibiotic therapy and treatment of patients with peptic disease symptoms, the incidence of gastric MALT lymphoma, and the percentage of gastric MALT lymphomas containing *H. pylori,* is declining.[12,17,18,43,44]

Campylobacter jejuni and Immunoproliferative Small Intestinal Disease

IPSID is a variant of MALT lymphoma involving the small intestine that is often associated with secretion of an abnormally truncated immunoglobulin alpha heavy chain without accompanying light chains (alpha heavy chain disease).[20,21,31] IPSID has a restricted geographic and socioeconomic distribution, supporting the role of environmental factors in its pathogenesis. An infectious etiology has long been suspected, and it is recognized that the early stages of IPSID may respond to antibiotic treatment (tetracycline or metronidazole and ampicillin), with durable remissions.[20,45-47] In 2004, Lecuit and associates reported detection of *Campylobacter jejuni* DNA in five of seven patients with IPSID and resolution of symptoms in one index patient after antibiotic therapy against *Campylobacter*.[48] A subsequent case report also described resolution after antibiotic therapy.[49] Although these findings suggested that *C. jejuni* may play the same role in IPSID as *H. pylori* does in gastric MALT lymphoma, there is only limited additional evidence supporting this hypothesis. In a polymerase chain reaction (PCR) study published in abstract format, Diss and colleagues confirmed the presence of *C. jejuni* 16s rDNA in one-half of IPSID samples, but also detected the organism in other small intestinal lymphomas.[50] It is also documented that other microbes and parasites, including *Campylobacter coli,* may be isolated from the stool of patients with IPSID.[51,52] *C. jejuni* and *C. coli* are foodborne pathogens that commonly cause an acute enteritis that resolves within 1 to 2 weeks, although in developing countries infection with these organisms is hyperendemic, with repeated exposures from a young age.[53] *Campylobacter* infection is also known to occasionally precipitate reactive (aseptic) arthritis and Guillain-Barré

syndrome.[53] In most individuals, excretion of the bacteria resolves within a matter of weeks, but prolonged colonization may occur in patients with underlying immunodeficiency.[53,54] This finding has led to a current hypothesis that IPSID develops in individuals with an impaired gastrointestinal immune response, either from previous infections or an underlying genetic predisposition, who have difficulty clearing *C. jejuni*. This chronic small bowel infection may then produce the chronic antigenic stimulation required for MALT lymphoma development.[55,56] However, additional studies are required to further clarify the role of *Campylobacter* in the development of IPSID.

Borrelia burgdorferi and Primary Cutaneous Marginal Zone Lymphoproliferative Disorder

Borrelia burgdorferi is an *Ixodes* tick-borne spirochete associated with several dermatologic conditions including erythema migrans, lymphadenosis benigna cutis (pseudolymphoma), and acrodermatitis chronica atrophicans.[31,53] In 1991, Garbe and colleagues[57] first described four cases of cutaneous lymphoma, later characterized as primary cutaneous marginal zone lymphoproliferative disorder (pcMZLPD), associated with *B. burgdorferi* infection. In 1997, Kutting and associates[58] reported clinical cures of two cases of pcMZLPD after eradication of *B. burgdorferi* with the antibiotic cefotaxime. Several additional reports have followed from Europe, including one study describing *B. burgdorferi* infection in up to 42% of patients with pcMZLPD from the Scottish Highlands.[59,60] However, there is substantial geographic variability, and other studies of pcMZLPD that include

patients from Europe, Asia, and the United States have not found an association with *B. burgdorferi*.[61,62] One large Scandinavian case-control study also found no association of tick bite or the presence of anti-*Borrelia* antibodies with overall risk of marginal zone lymphoma, although specific results for pcMZLPD were not reported.[63]

Chlamydia psittaci and Ocular Adnexal MALT Lymphoma

Chlamydia psittaci, an organism that infects a wide range of birds, is the etiologic agent of psittacosis in humans, which may manifest as an influenza-like syndrome, bronchopneumonia, or more severe illness.[53] In 2004, Yeung and coworkers described a single case of association between a chlamydial organism and a conjunctival MALT lymphoma.[64] Later that year, Ferreri and colleagues,[65] in a PCR study, reported an association between *C. psittaci* and ocular adnexal MALT lymphoma in 80% of cases and went on to demonstrate the complete response of four cases after eradication of *C. psittaci* with doxycycline.[66] In 2008, Ferreri and associates reported the in vitro isolation and growth of *C. psittaci* from patients with ocular MALT lymphoma but not healthy controls.[67] A further study suggested that viable *C. psittaci* resided within the intratumoral monocytes/macrophages of these lymphomas.[68] In addition, *C. psittaci* DNA has been identified in MALT lymphomas at other sites, including lung, thyroid gland, salivary gland, and skin.[69,70] A patient who developed multiple *C. psittaci*–related ocular adnexal MALT lymphomas and pulmonary diffuse large B-cell lymphoma after prolonged exposure to an infected animal has also been reported.[71] Although all of this provides evidence that would support a

pathogenic association between *C. psittaci* and MALT lymphoma, there is substantial geographic variability, with high prevalence rates of *C. psittaci* infection in ocular adnexal MALT lymphomas reported from Italy, Austria, and South Korea, and a much lower incidence in the United States, Japan, and China.[72-75]

Achromobacter xylosoxidans and Pulmonary MALT Lymphoma

Achromobacter xylosoxidans is a gram-negative bacterium that is widely distributed in moist environments and soil, and is a well-known opportunistic pathogen that is recurrently isolated from the sputum of patients with cystic fibrosis.[76,77] *A. xylosoxidans* DNA was first described in pulmonary MALT lymphomas in 2008,[78] with a subsequent study in 2014 demonstrating its DNA in 46% of pulmonary MALT lymphomas from six European countries.[76] This was significantly different than the rate of *A. xylosoxidans* infection in control lung tissues (18%). Although data is very limited, there appear to be regional differences in the prevalence of *A. xylosoxidans* infection, ranging from 67% of pulmonary MALT lymphomas in Italy to 2% of cases in Japan.[76,79] There are currently no additional studies definitively demonstrating a causal relationship between *A. xylosoxidans* and pulmonary MALT lymphoma.

Hepatitis C Virus

Hepatitis C virus (HCV) is a hepatotropic and lymphotropic RNA virus that is associated with the development of B-cell non-Hodgkin lymphomas.[80] Multiple studies have shown an increased risk of MALT lymphoma in individuals who are HCV seropositive, and a study from Italy documented HCV infection in 35% of patients with

nongastric MALT lymphomas.[81-83] However, there are well-recognized geographic variations in the prevalence of HCV infection, which affect the prevalence of HCV-associated lymphoma.[82,84,85] MALT lymphomas arising in HCV-positive individuals are most common at nongastric sites, most frequently involving skin, salivary glands, and ocular adnexal sites.[81] The biological mechanisms underlying HCV-associated lymphomagenesis are not clarified. Studies have shown that antiviral therapy may result in complete or partial remission of B-cell non-Hodgkin lymphomas, including MALT lymphomas, in HCV-positive patients, while this response is not observed in HCV-negative patients.[86-89] A systematic review documented complete responses to antiviral therapy in 75% of HCV-positive patients with lymphoma.[86] In addition, viral elimination induced by interferon therapy has been associated with a reduced incidence of lymphoma in one study.[90]

Epstein-Barr Virus

In recent years, rare MALT lymphomas associated with Epstein-Barr virus (EBV) have been described in patients with an underlying immunodeficiency. Although initially described in posttransplant patients, with subcutaneous and soft tissue localization,[91] additional reports have recognized these lymphomas at other extranodal sites and in other settings, including iatrogenic immunosuppression for autoimmune disease, prior chemotherapy, congenital immunodeficiency, and increased age.[92,93] An EBV latency pattern I or II has been documented in the cases studied.[91,93] These EBV-positive MALT lymphomas generally follow an indolent clinical

course, with a response to immune reconstitution documented in a subset of cases.[91,93]

Autoimmune Disorders

Individuals with B-cell activating autoimmune diseases, such as Sjo¨gren syndrome, Hashimoto's disease, and systemic lupus erythematosus, are at an increased risk for the development of MALT lymphoma.[83,94-96] Although it is impossible to entirely parse out the exact contributions of the underlying autoimmune disease, treatments, and other host factors, it is thought that the level of disease severity and inflammation is the main driver of lymphomagenesis.[16,97] Acquired MALT is a feature of both Sjo¨gren syndrome and Hashimoto's disease.[24,25] A study proposed a model whereby the lymphoepithelial lesions of LESA provide paracrine stimulation to neoplastic B cells via GPR34, a member of the class A G-protein-coupled receptor superfamily.[98] *GPR34* alterations (mutations or translocations) are enriched in salivary gland MALT lymphomas (19% of cases).[99] Sjo¨gren syndrome is strongly associated with salivary gland lymphoma, and a pooled analysis of almost 30,000 individuals in Europe, North America, and Australia found a 1000-fold increased risk of parotid gland MALT lymphomas.[83,94,96] Similarly, patients with Hashimoto's disease have a 67-fold increased risk of thyroid lymphoma, most commonly as a MALT lymphoma or transformed MALT lymphoma.[95,100] Individuals with systemic lupus erythematosus have about a 3-fold increased risk of developing non-Hodgkin lymphoma, and in particular diffuse large B-cell lymphomas and MALT lymphomas.[83,94,96,101] Although there is an approximately 2-fold

increased risk of lymphoma in patients with rheumatoid arthritis, these are frequently diffuse large B-cell lymphomas, and a definite association with MALT lymphomas is not established.[102-104] T-cell activating autoimmune conditions, such as inflammatory bowel disease, multiple sclerosis, sarcoidosis, psoriasis, and type 1 diabetes, are generally not associated with the development of MALT lymphoma.[83,94,96]

Histopathology of Acquired Malt

Tissues in which MALT lymphomas occur seem to mount a stereotypic response to certain known and unknown agents with the accumulation of lymphoid tissue that forms Peyer's patch–like structures. The two sites in which this is best illustrated are the salivary gland and the stomach.

Salivary Gland Acquired MALT (Lymphoepithelial Sialadenitis)

Apart from the intrasalivary gland lymph nodes, especially in the parotid glands, normal salivary glands contain no organized lymphoid tissue. Lymphoid tissue may accumulate in the salivary glands as a result of chronic inflammation of varying causes. Chronic inflammation after long-standing sialolithiasis is one example in which numerous lymphoid follicles may be present around dilated ducts that often contain a purulent exudate. This appearance is quite different from the chronic inflammation associated with established Sjögren syndrome. In the earlier phase of this condition, isolated salivary ducts are dilated and surrounded by a lymphoid infiltrate that contains lymphoid follicles and recapitulates the structure of

Peyer's patches (see **Fig. 18-2B**). Small, focal B-cell aggregates are characteristically seen in the duct epithelium, reminiscent of the dome epithelium of the Peyer's patch. These B cells are slightly larger than typical small lymphocytes of the mantle zone; they often have more abundant pale-staining cytoplasm and nuclei with an irregular outline (see **Fig. 18-2C**). The cytologic appearance and immunophenotype of these cells suggest that they are marginal zone B cells. Plasma cells are also present and tend to concentrate around the duct. As the disease progresses, the ducts condense, with partial or complete loss of their lumens, and form lymphoepithelial lesions that consist of cohesive aggregates of duct epithelium containing variable numbers of marginal zone B lymphocytes (see **Fig. 18-2D**),[25,105] often associated with atrophy or, not infrequently, fatty replacement of acinar tissue. These Peyer's patch–like lesions may fuse to form larger islands of lymphoid tissue, and some of the lymphoepithelial islands may develop into cystic structures, resulting in a multicystic gland. Not all patients with this pattern of lymphoid infiltration in salivary glands are necessarily suffering from Sjögren syndrome. Identical changes have been described in patients with a variety of other autoimmune diseases and sometimes in those with no evidence of an associated disorder. Hence the generic terms *benign lymphoepithelial lesion* and *myoepithelial sialadenitis* are now more appropriately termed *lymphoepithelial sialadenitis (LESA)*.[106]

Immunohistochemistry shows that the germinal centers are immunophenotypically identical to those in the Peyer's patches and lymph nodes. They are surrounded by CD20-positive, IgM-positive, IgD-positive mantle zone cells that express polytypic light chains.

The infiltrate of small lymphocytes present between the follicles is composed principally of CD3-positive T cells, which tend to concentrate around the B-cell follicles and are often accompanied by polytypic plasma cells. In some cases, large numbers of T cells are present and may even outnumber the B cells.

Overall, the border between LESA and lymphoma is blurred, and it can be difficult to differentiate between them in some cases. Immunoglobulin gene rearrangement studies, which demonstrate clonal B cells in MALT lymphoma, may also show clonal B cells in some cases of LESA.[107,108] Whenever a diagnosis of LESA is made, the question of lymphoma remains open, to a certain extent.

Helicobacter pylori Gastritis

Because of its ability to withstand a low pH, *H. pylori* is the one organism, apart from some other rare *Helicobacter* species, that can survive in the human gastric mucosa. The prevalence of *H. pylori* gastritis in any given population varies from 20% to 100%, depending on the locality and the age cohort.[44,109] With some exceptions, the prevalence of gastric MALT lymphoma is related to that of *H. pylori* gastritis. Typically, infection results in active chronic inflammation with B-cell follicles and the formation of a lymphoepithelium by B-cell infiltration of glands immediately adjacent to the follicles—features of acquired MALT. Between the follicles, the gastric mucosa is infiltrated by T lymphocytes, plasma cells, macrophages, and occasional collections of neutrophils. The lymphoid infiltrate may be extremely florid and is sometimes difficult to distinguish from MALT lymphoma, especially when there are large, fused sheets of mantle zone cells in biopsy fragments.

Immunohistochemistry is useful in delineating the B-cell follicles and distinguishing the IgM-positive, IgD-positive mantle zone cells from the IgM-positive, IgD-negative MALT lymphoma cells. Staining for immunoglobulin light chains can be useful in detecting monotypic B cells and plasma cells in some cases of MALT lymphoma; however, the presence of polyclonal plasma cells does not exclude the diagnosis. PCR clonality studies of small endoscopic biopsies present particular technical challenges, and performing analysis in duplicate is critical to eliminate false-positive (so-called "pseudoclonal") results.[110,111] Though some studies have reported clonal results in gastric biopsies from patients with *H. pylori* gastritis,[112,113] when PCR is performed in duplicate and properly interpreted, clonal B-cell populations are extremely uncommon.[114,115] It is noteworthy that in patients with clonal gastritis who later developed overt MALT lymphoma, the identical monoclonal B-cell population has been detected in both lesions.[40]

Pathology of Malt Lymphoma

Macroscopic Appearance

Macroscopically, MALT lymphomas are quite variable, sometimes forming distinct tumoral masses, and other times grossly resembling the inflammatory lesions that may give rise to MALT lymphoma. Gastric MALT lymphoma, for example, may form a single dominant mass but often results in only slightly raised congested mucosa, with superficial erosions indistinguishable at endoscopy from chronic gastritis.[116] MALT lymphomas are often multifocal, with small, even microscopic foci of clonally identical lymphoma scattered throughout the organ involved.[117]

Histopathology

Although there are some site-specific morphologic differences, the histologic findings in MALT lymphoma are generally similar in that the lymphoma recapitulates the organization of normal Peyer's patches, especially in the early stages of disease.[118,119] The neoplastic B cells proliferate around reactive B-cell follicles, usually external to a preserved follicular mantle, in a marginal zone distribution; they spread out to form larger confluent areas that eventually may overrun some or most of the follicles (see **Fig. 18-3**). Like benign marginal zone B cells, the neoplastic cells have pale cytoplasm with small-to-medium-sized, slightly irregularly shaped nuclei containing moderately dispersed chromatin and inconspicuous nucleoli. These cells have historically been called centrocyte-like because of their resemblance to germinal center centrocytes. The accumulation of more abundant pale-staining cytoplasm may lead to a monocytoid appearance of the lymphoma cells, especially in some anatomic sites such as the parotid gland where a very monocytoid appearance is the norm. In some cases, the cells more closely resemble small lymphocytes. Scattered large cells resembling centroblasts or immunoblasts are usually present, but these are in the minority and do not form confluent clusters or sheets. Plasma cell differentiation is present in up to one-third of cases[120] and in gastric lymphomas tends to be maximal beneath the surface gastric epithelium.

At many extranodal sites, glandular epithelium is often invaded and destroyed by discrete aggregates of lymphoma cells, resulting in the so-called lymphoepithelial lesions. These are defined as aggregates of three or more neoplastic marginal zone lymphocytes within glandular epithelium, preferably associated with distortion or

necrosis of the epithelium. In gastric MALT lymphoma, these lesions are often accompanied by eosinophilic degeneration of the epithelium. Lymphoepithelial lesions, although highly characteristic of MALT lymphoma, especially gastric lymphoma, are not pathognomonic. In benign chronic gastritis, for example, small lymphoepithelial lesions may be present, often directly overlying reactive germinal centers. Lymphoepithelial lesions may be difficult to find or even absent in some MALT lymphomas, such as those of the small intestine and large intestine. In gastric MALT lymphoma, a histologic scoring system that incorporates the typical morphologic features (**Table 18-1**)[42] has been widely used in research studies; though providing a useful framework to gauge the degree of suspicion for MALT lymphoma on routine H&E (hematoxylin and eosin) sections, establishing a diagnosis in clinical practice requires immunophenotyping in addition to the H&E morphology.[121,122]

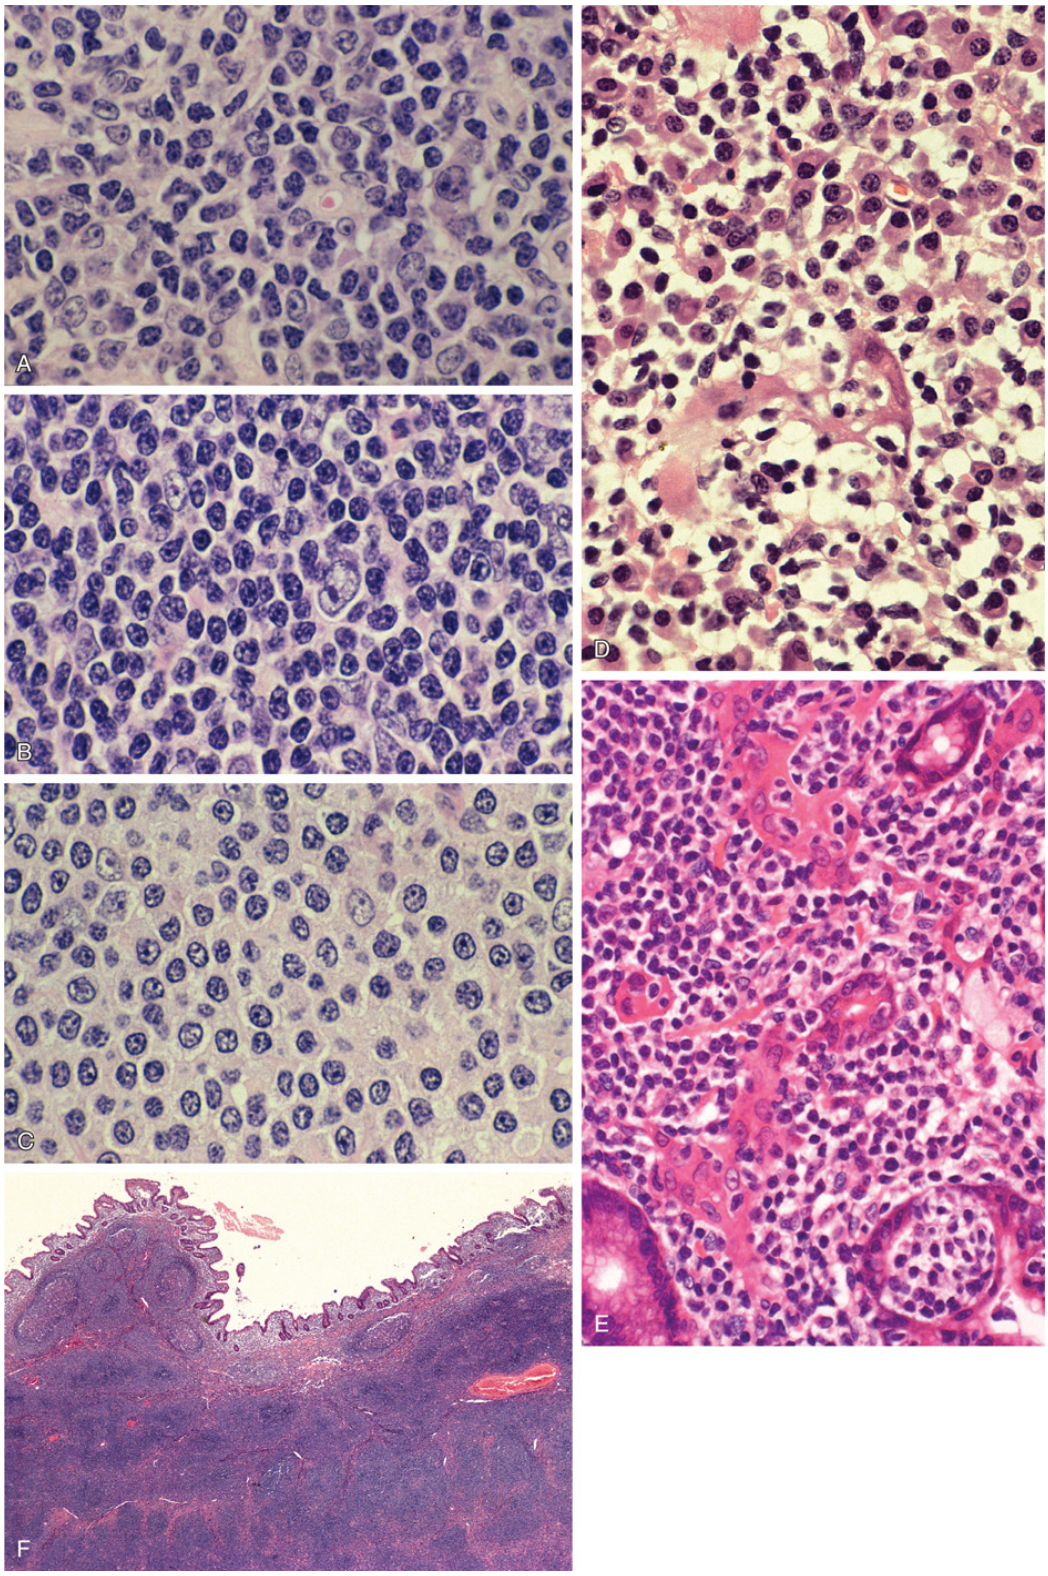

FIGURE 18-3 Morphology of B cells in gastric MALT lymphoma.A, The cells of

gastric MALT lymphoma have a centrocyte-like appearance, with irregularly shaped nuclei. **B,** The tumor cells in this MALT lymphoma more closely resemble small lymphocytes. Note the presence of occasional transformed cells. **C,** The neoplastic cells in this MALT lymphoma have acquired more abundant pale-staining cytoplasm, leading to a monocytoid appearance. **D,** Plasma cell differentiation in a case of gastric MALT lymphoma. A lymphoepithelial lesion is present *below*. **E,** The tumor cells in this gastric MALT lymphoma form prominent lymphoepithelial lesions, with distortion and eosinophilic degeneration of gastric glandular epithelium. **F,** The neoplastic cells in this MALT lymphoma encircle reactive B-cell follicles *(upper left)* and have replaced follicles, leading to a nodular appearance *below*.

Table 18-1

Use of Histology Score to Differentiate Gastric MALT Lymphoma From Chronic Gastritis

Score	Interpretation	Histology
0	Normal	Scattered plasma cells in lamina propria. No lymphoid follicles.
1	Chronic active gastritis	Small clusters of lymphocytes in lamina propria. No lymphoid follicles. No LELs.
2	Follicular gastritis	Prominent lymphoid follicles with surrounding mantle zone and plasma cells. No LELs.
3	Suspicious, probably reactive	Lymphoid follicles surrounded by small lymphocytes that infiltrate diffusely in the lamina propria and occasionally into epithelium.
4	Suspicious, probably lymphoma	Lymphoid follicles surrounded by marginal zone cells that infiltrate diffusely in the lamina propria and into epithelium in small groups.
5	MALT lymphoma	Presence of dense, diffuse infiltrate of marginal zone cells in lamina propria with prominent LELs.

LEL, Lymphoepithelial lesion; *MALT,* mucosa-associated lymphoid tissue.

Modified from Wotherspoon, et al.[42]

Lymphoma cells sometimes specifically colonize germinal centers of the reactive follicles (see **Fig. 18-4**).[123] Usually this results in a vaguely nodular or follicular pattern. In some cases, the lymphoma cells specifically target germinal centers, where they may undergo large cell transformation or plasma cell differentiation. Importantly, the presence of large cells confined to preexisting germinal centers is not considered evidence of transformation to large B-cell lymphoma.

As with other small B-cell neoplasms, MALT lymphoma may undergo transformation to diffuse large B-cell lymphoma.[32,121,124] Most studies report large cell transformation in <10% of cases, a lower incidence than in many other small B-cell neoplasms. The diagnosis of large cell transformation requires the presence of solid or sheetlike proliferations of large transformed cells. This transformation may or may not result in complete overgrowth of the preceding MALT lymphoma. In the latter cases, the diagnosis of both diffuse large B-cell lymphoma and concurrent MALT lymphoma should be rendered, and the relative proportions of both should be documented.[121]

Morphology of Gastric MALT Lymphoma Following Eradication of *Helicobacter pylori*

Approximately 75% of gastric MALT lymphomas respond to the eradication of *H. pylori,* with regression of the tumor over a period of up to 18 months.[42,125] Repeated endoscopy with biopsy is

necessary to determine whether the lymphoma is responding (**Fig. 18-5**). The endoscopic appearance may revert to normal within 6 months of the eradication of *H. pylori*. There is often a noticeable change in the histologic appearance of the biopsy within a few weeks, with gradual clearance of the lymphoma in the following months. Initially, the inflammatory infiltrate accompanying the lymphoma disappears, with an empty-appearing eosinophilic lamina propria that may contain lymphoid aggregates (**Fig. 18-6**). These aggregates are composed of small B lymphocytes without significant numbers of large cells and gradually become smaller over time. Immunohistochemistry shows that they contain few accompanying T cells and have a low proliferation fraction. Such aggregates may not disappear altogether and may persist for long periods at the base of the mucosa or in the submucosa. The Groupe d'Etude des Lymphomes de l'Adulte (GELA) has proposed a histologic scoring system that defines four categories for posttreatment evaluation: complete histologic remission, probable minimal residual disease, responding residual disease, and no change (**Table 18-2**).[126,127] Although this schema is employed in many research studies, it is not widely used in routine clinical practice.

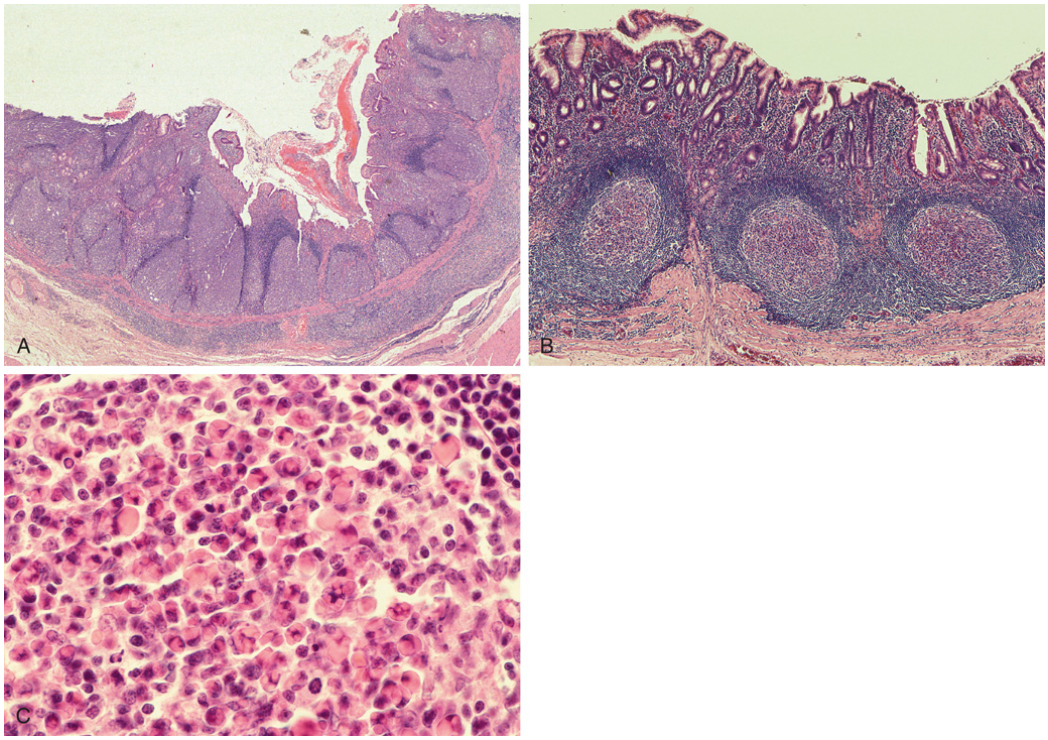

FIGURE 18-4 MALT lymphoma: relationship to B-cell follicles.A, The germinal centers of reactive B-cell follicles are colonized by transformed MALT lymphoma cells, resulting in an appearance simulating follicular lymphoma. **B,** The germinal centers of these reactive follicles are colonized by MALT lymphoma cells that have undergone plasmacytoid differentiation. **C,** Higher magnification of the germinal centers showing the cells stuffed with eosinophilic immunoglobulin.

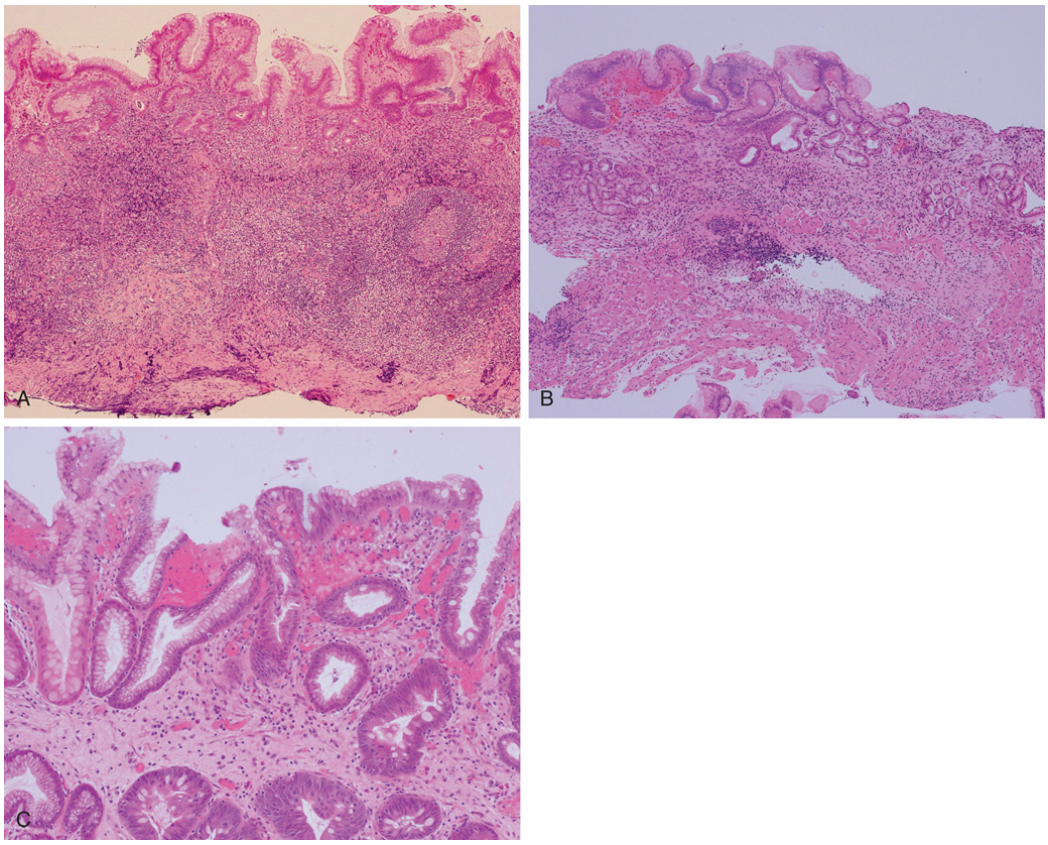

FIGURE 18-6 **A,** Gastric biopsy of a MALT lymphoma. **B,** Repeat biopsy 7 months after eradication of *Helicobacter pylori*. The lymphoma has regressed, leaving small lymphoid aggregates. **C,** Higher magnification showing scattered small lymphocytes in an empty-appearing lamina propria.

Despite histologic regression, a persistent neoplastic clone may be detected by PCR in the majority of patients after *Helicobacter* eradication.[128] Persistent clones in the absence of histologic disease have also been reported in some studies after radiation or chemotherapy.[129-131] Such cases suggest that the neoplastic clone

can remain quiescent in the absence of antigenic stimulation provided by *Helicobacter* infection.

Dissemination

The frequency and pattern of dissemination of MALT lymphoma vary with the site of disease, and involvement of more than one extranodal site has been reported in 20% to 30% of cases.[132,133] Most gastric MALT lymphomas are stage I when they present, but between 4% and 35% have disseminated to regional lymph nodes, and approximately 5% have disseminated to the bone marrow at the time of diagnosis.[134-136] More than 90% of salivary gland MALT lymphomas present at stage I, whereas 44% of pulmonary MALT lymphomas have disseminated to mediastinal lymph nodes at the time of diagnosis.[137] Approximately 20% of lymphomas of the ocular adnexa are beyond stage I at diagnosis.[138] In one study that grouped all MALT lymphomas together regardless of the site of origin, the disease had disseminated beyond the site of origin in 34% of cases.[139] MALT lymphomas also appear to disseminate to other sites where MALT lymphomas occur. Gastric MALT lymphomas, for example, tend to disseminate to the small intestine, salivary gland, and lung. Interestingly, molecular studies in patients with MALT lymphomas involving more than one MALT site have reported that some cases may represent two independent, clonally unrelated lymphomas rather than true dissemination of one lymphoma.[140]

Table 18-2

GELA, Groupe d'Etude des Lymphomes de l'Adulte.

When MALT lymphomas disseminate to lymphoid tissue, including lymph nodes and spleen, they specifically invade the marginal zone (**Fig. 18-7**). This can lead to a deceptively benign or reactive appearance, especially in mesenteric lymph nodes, where a marginal zone is normally present. Immunohistochemistry for immunoglobulin light chains can be very helpful in discriminating normal marginal zone from disseminated MALT lymphoma. Subsequently, the lymphoma in the marginal zones expands to form more obvious sheets of interfollicular lymphoma. Occasionally, follicular colonization in involved lymph nodes can lead to an appearance that simulates follicular lymphoma (FL).

Immunohistochemistry

The immunophenotype of MALT lymphoma essentially recapitulates that of marginal zone B cells. The B cells are CD20+, PAX5+, CD79a+, CD21+, CD35+, CD5−, CD10−, CD23−, cyclin D1−, and SOX11−.[141,142] CD43 is aberrantly expressed in approximately 50% of cases, and expression of CD11c is variable. The tumor cells typically express IgM, less often express IgA or IgG, are IgD-negative, and show immunoglobulin light chain restriction. A significant intratumoral population of CD3-positive, predominantly CD4-positive T cells is frequently present. Expanded meshworks of follicular dendritic cells are typically detected with antibodies CD21 and CD23, corresponding to follicles that are colonized or overrun by the lymphoma cells. Variable numbers of BCL6-positive, CD10-positive follicle center cells may be seen in these areas, whereas the neoplastic cells outside of germinal centers are negative for these antigens.

Newer markers proposed as diagnostically useful in the workup of suspected marginal zone lymphomas include MNDA and IRTA1.[32,143] MNDA expression has been reported in 68% to 95% of MALT lymphomas, 5% to 21% of FLs, and 37% to 100% of various other small B-cell lymphomas.[144,145] The demonstration of MNDA expression may therefore be useful in the specific differential diagnosis of MALT lymphoma versus FL. IRTA1 expression has been reported in 52% to 93% of MALT lymphomas versus <10% of other small B-cell neoplasms.[145,146]

Genetic Features of Malt Lymphoma

Antigen Receptor Genes

In MALT lymphomas, immunoglobulin heavy and light chain genes are clonally rearranged and show evidence of somatic hypermutation in their variable regions, consistent with a postgerminal center memory B-cell origin.[147] Ongoing mutations are thought to occur in most cases.[148] As it is frequently challenging to distinguish between hyperplastic proliferations of acquired MALT versus extranodal MALT lymphoma, especially in small biopsy specimens, molecular analysis is frequently employed during diagnostic evaluation. When testing is performed with BIOMED-2/EuroClonality primer sets targeting IGH and IGK following consensus guidelines,[111] the frequency of false negative results appears to be low (<5%). However, assays employing IGH primers alone may miss monoclonality in up to 15% of cases of overt lymphoma.[149] Monoclonal results may also be seen as a spurious finding (a false positive result) in some samples of reactive MALT tissue, such as in chronic gastritis. The frequency of false positive results varies widely

across laboratories, suggesting that variations in technique may be a factor. For these reasons, a diagnosis of MALT lymphoma should never be diagnosed based upon clonal PCR results alone in the absence of histopathologic abnormalities. Similarly, clonal rearrangements may remain detectable by PCR after eradication of *H. pylori* for the treatment of MALT lymphoma, and this finding appears to lack clinical significance in the absence of histologic features of persistent lymphoma.[127]

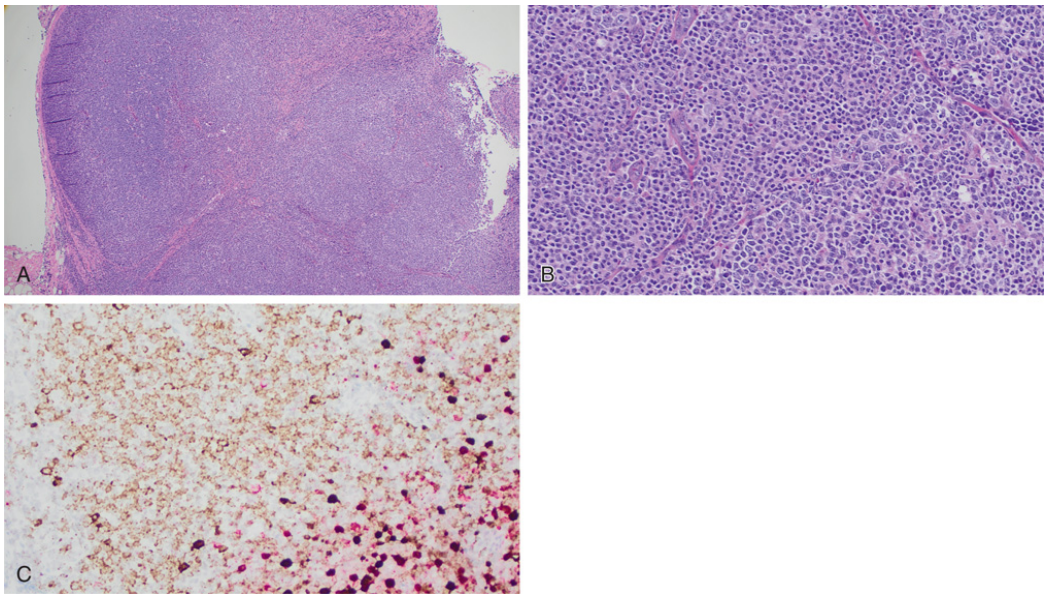

FIGURE 18-7 **A,** Gastric lymph node from a case of MALT lymphoma showing a vaguely nodular growth pattern. **B,** At higher magnification, the neoplastic marginal zone cells *(upper left)* surround a residual germinal center *(right)*. **C,** Ultrasensitive in situ hybridization stain for kappa *(brown)* and lambda *(red)* shows kappa monotypic lymphoma cells surrounding a polytypic germinal center.

Sequencing studies of the immunoglobulin genes in MALT lymphomas have shown that cases arising at a given anatomic site show characteristic bias in the usage of specific IGVH gene segments. For example, cases of gastric MALT lymphoma show overrepresentation of IGHV3-7 and IGHV1-69, while cases arising in the salivary gland are biased toward IGHV1-69 and those in the ocular adnexa toward IGHV4-34.[150,151] Comparisons of the resulting amino acid sequences have shown evidence of positive and negative

selection for replacement mutations, consistent with antigen-driven selection. These findings emphasize the role of an antigen-directed response in the evolution of the neoplastic clone. In some cases this antigen may represent an underlying infectious agent, such as *H. pylori* in gastric MALT lymphoma, and in other cases the initial response may be against an autoantigen.[152]

Genetic Abnormalities

A number of genetic abnormalities are recurrent in MALT lymphoma, including trisomies of chromosomes 3, 12, and 18, which also occur in primary nodal marginal zone lymphomas and splenic marginal zone lymphomas. Balanced translocations specifically associated with extranodal MALT lymphoma include t(11;18)(q21;q21) *BIRC3*::*MALT1,* t(14;18)(q32;q21) *IGH*::*MALT1,* t(1;14)(p22;q32) *BCL10*::*IGH*, and t(3;14)(p14;q32) *FOXP1*::*IGH*. Next-generation sequencing studies have shown a large number of recurrent mutations including *TNFAIP3 (A20)*, *CREBBP, KMT2C, TET2, SPEN, KMT2D, LRP1B,* and *PRDM1*.[151] Many of these genetic abnormalities result in activation of the NF-κB signaling pathway, which is thought to represent a major mechanism of oncogenesis in MALT lymphoma. Notably, the frequency of these various cytogenetic and molecular abnormalities varies with the anatomic site of origin (**Table 18-3**). Details of the most common abnormalities are discussed further.

t(11;18)(q21;q21) *BIRC3*::*MALT1* is the most frequent translocation in MALT lymphoma, being found in approximately 40% of pulmonary cases and 30% of gastric MALT lymphomas, with a lower incidence elsewhere.[150,153] This translocation produces a

functional *BIRC3*::*MALT1* fusion protein that leads to constitutive activation of NF-κB signaling. In gastric MALT lymphoma, the *BIRC3*::*MALT1* fusion is associated with advanced stage disease and decreased response to antibiotic therapy against *H. pylori*. Routine testing for *BIRC3*::*MALT1* is therefore widely performed in the setting of newly diagnosed gastric MALT lymphoma. This abnormality may be detected from formalin-fixed paraffin embedded tissues using RT-PCR assays or through fluorescence in situ hybridization (FISH) studies with either *BIR3*::*MALT1* fusion probes or *MALT1* break-apart probes.

Table 18-3

Molecular/Cytogenetic Abnormalities in Extranodal MALT Lymphomas

Summarized from Vela et al,[198] Streubal et al,[156] and Remstein et al.[199]

The t(14;18)(q32;q21) *IGH*::*MALT1* translocation has been reported to be the second-most common translocation in extranodal MALT lymphoma.[150,153,154] This abnormality places the intact *MALT1* gene under the IGH enhancer region, resulting in overexpression of the MALT1 protein and enhanced NF-κB activity. It should be noted that this translocation involves the same chromosomal breakpoints as the much more common t(14;18)(q32;q21) *IGH*::*BCL2* associated with FL and diffuse large B-cell lymphoma.[154] Definitive recognition of this translocation therefore requires the use of FISH or other molecular methods.

t(1;14)(p22;q32) *BCL10*::*IGH* places the *BCL10* gene under control of the IGH enhancer and leads to overexpression of the BCL10 protein.[150,153,155,156] BCL10 serves to link signaling from the B-cell antigen receptors to the canonical NF-κB signaling pathway, and the t(1;14) therefore results in constitutive activation of this pathway. The t(1;14) is rare, being reported in 1% to 2% of MALT lymphomas.[153,156] The clinical effect of this translocation in MALT lymphoma is not well characterized to date because of its rarity; however, nuclear overexpression of the BCL10 protein, which may occur either as a result of the t(1;14) or through other mechanisms, has been associated with decreased response to antibiotic therapy in gastric MALT lymphoma.[157-160]

TNFAIP3 (previously known as *A20*), which is located on chromosome 6q23, is recurrently mutated or deleted in extranodal MALT lymphomas.[150,151] *TNFAIP3* serves as a negative regulator of

the NF-κB pathway, and deletion of this locus or the presence of inactivating mutations leads to enhanced activation of this signaling pathway. Abnormalities of *TNFAIP3* have been reported most frequently in cases lacking any of the translocations described, with highest frequencies reported in ocular adnexa, salivary gland, and thyroid.

Postulated Cell of Origin

The architectural features of MALT lymphoma, particularly early cases, show quite clearly that the neoplastic cells are infiltrating the marginal zone around B-cell follicles. In non-neoplastic lymphoid tissue, a prominent marginal zone is present in the spleen, Peyer's patches, and mesenteric lymph nodes. This allows a comparison of the cytology and immunophenotype of normal marginal zone cells with those of MALT lymphoma (**Fig. 18-8**). Cytologically, MALT lymphoma cells bear a close resemblance to marginal zone cells. Both are slightly larger than small lymphocytes and have a slightly irregular nuclear outline and moderate amounts of pale-staining cytoplasm. Interestingly, in both Peyer's patches and LESA, collections of marginal zone cells are found within the dome and ductal epithelium, respectively. The immunophenotypes of cells of the marginal zone and MALT lymphoma are virtually identical, with both expressing CD20 and other pan–B-cell antigens, CD21, CD35, and IgM, but not IgD.[161,162]

Clinical Course

MALT lymphomas are among the most indolent of all lymphomas and have a good prognosis, regardless of stage. Five-year and ten-

year overall survival rates exceeding 80% are the rule, although progression-free survival may be somewhat lower.[139,163] Patients with primary cutaneous disease, despite frequent cutaneous relapses, have an extremely indolent clinical course with 5-year disease-specific survival approaching 100% in most large studies.[164,165] Given this extremely indolent behavior, primary cutaneous marginal zone (MALT) lymphoma is now recognized as primary cutaneous marginal zone lymphoproliferative disorder (pcMZLPD) rather than an overt lymphoma in the 2022 ICC.[4] Although most patients present with localized disease, involvement of multiple mucosal sites at initial presentation or during the disease course is not uncommon in noncutaneous MALT lymphomas, and is not associated with a poorer outcome.[133,139,163,166] The presence of lymph node or bone marrow involvement at diagnosis has been associated with a worse prognosis in some studies, but not in others.[139,163,166] Patients with pcMZLPD by definition do not have extracutaneous disease at initial presentation, and dissemination to noncutaneous sites during the course of disease is rare.[165,167-169] Transformation to diffuse large B-cell lymphoma is reported in <10% of MALT lymphomas, and is associated with an adverse outcome.[139,166,170,171] Preferred treatment modalities differ according to the site of origin and vary from “watch and wait” to surgery, antibiotic or antiviral therapy, radiotherapy, and immunochemotherapy.[32,142,172,173]

The treatment of gastric MALT lymphoma has attracted considerable attention since the initial published report that the lymphoma may regress after eradication of *H. pylori* with antibiotics. The most recent recommended staging systems for gastric MALT lymphomas include endoscopy with multiple biopsy

specimens from the stomach, duodenum, and gastroesophageal junction, and from each site with an abnormal appearance.[142,172] Endoscopic ultrasound is helpful for identifying dissemination to perigastric lymph nodes and to assess the depth of gastric wall infiltration; studies have shown that the lymphoma is less likely to respond to eradication of *H. pylori* if it has invaded beyond the submucosa.[127,174,175] The follow-up of MALT lymphoma patients after eradication of *H. pylori* is rather complex, requiring repeated gastroscopy with biopsy. Cases that have transformed to a diffuse large B-cell lymphoma are unlikely to respond to *H. pylori* treatment, although there are reports of complete regression in such cases.[176,177] The presence of t(11;18)(q21;q21) *BIRC3*::*MALT1* in gastric MALT lymphomas is associated with more advanced disease, a lack of associated *H. pylori* infection, and failure to respond to eradication of *H. pylori* when present.[32,178] Recent National Comprehensive Cancer Network guidelines suggest evaluation of t(11;18)(q21;q21) *BIRC3*::*MALT1* with FISH or PCR in cases that are *H. pylori* positive.[173] Antibiotic treatment with involved-site radiotherapy (preferred) or rituximab is recommended for *H. pylori*–positive patients who harbor the translocation.

node *(left)* compared with the cells of a gastric MALT lymphoma *(right)*.

Differential Diagnosis

Reactive Versus Neoplastic MALT

The distinction between acquired MALT, the precursor of MALT lymphoma, and MALT lymphoma in the early stages of evolution often gives rise to diagnostic difficulty. This is particularly true of gastric and salivary gland MALT lymphomas. Though acquired MALT in the stomach may harbor a lymphoepithelium adjacent to follicles mimicking the lymphoepithelial lesion characteristic of MALT lymphoma (**Fig. 18-9**), there should not be an extensive infiltrate of B cells external to the IgD-positive, IgM-positive mantle zones or an associated monotypic plasma-cell population; an expanded B-cell infiltrate in the lamina propria outside of follicles is more indicative of a MALT lymphoma (see **Table 18-1**).[42,179] The earliest sign of lymphoma in salivary glands is an extension of the intraepithelial B cells around the duct, the lumen of which is often partly obliterated by epithelial cells, to form halo-like infiltrates of monocytoid or centrocyte-like B cells around the duct (**Fig. 18-10**).[180] The cells constituting the halos are immunoglobulin light chain restricted and generally IgM-positive.[25] As the MALT lymphoma further develops, the halos surrounding lymphoepithelial lesions expand and become confluent. A diagnosis of overt MALT lymphoma is not warranted in lymphoproliferations that lack confluent, broad swaths of monocytoid- or centrocyte-like cells, or associated monotypic plasma cells.[105,107,181]

In the distinction between acquired MALT and MALT lymphoma, demonstration of clonality by virtue of light chain restriction of B cells or plasma cells, either by immunohistochemistry/in situ hybridization (paraffin sections) or by flow cytometry, can be diagnostic. Co-expression of CD43 by B cells is a useful hint that the B-cell population is neoplastic, although CD43 co-expression on B cells has also been described in some cases of LESA, and on subsets of reactive B cells and plasma cells.[107,182-184] Use of PCR for IGH and IGK rearrangements to discriminate reactive lymphoid infiltrates from MALT lymphoma is somewhat controversial. Although a positive PCR result is strong evidence of lymphoma in a case with suspicious morphologic and immunophenotypic features, it is well recognized that clonal B-cell populations may be detected in reactive lymphoproliferations at extranodal sites, including in over 50% of LESA.[107,108,181,185] The detection of a clonal cytogenetic abnormality by FISH may be helpful to confirm the diagnosis of MALT lymphoma, although the presence of these alterations is quite variable based on anatomic site (see **Table 18-3**).

MALT Lymphoma Versus Atypical Marginal Zone Hyperplasia

There are rare atypical marginal zone hyperplasias that may mimic MALT lymphoma.[186-191] Primarily reported in children, these atypical hyperplasias involve sites of native MALT (tonsils, adenoids, and appendix), anatomic locations infrequently involved by MALT lymphoma. First described in 2004 by Attygalle and colleagues,[186] these lymphoproliferations consist of a follicular hyperplasia with expansion of the marginal zones by centrocyte-like B cells admixed

with variable numbers of large, transformed cells. Some follicles have a moth-eaten appearance consistent with follicular colonization, and most cases show a component of intraepithelial B cells reminiscent of lymphoepithelial lesions. The marginal zone and intraepithelial B cells in these lymphoproliferations also generally demonstrate lambda light chain restriction by immunohistochemistry/in situ hybridization or flow cytometry, and may express CD43.[186,187,190,191] Although these histologic and immunophenotypic features raise suspicion for a MALT lymphoma, atypical marginal zone hyperplasias are differentiated by the lack of B-cell clonality with PCR studies for IGH, IGK, and IGL.[186,190,191] The benign nature of these atypical hyperplasias is further supported by clinical outcomes, with patients remaining alive with no evidence of disease, without lymphoma-directed treatment, at a median follow-up of 39 months.[186,190,191]

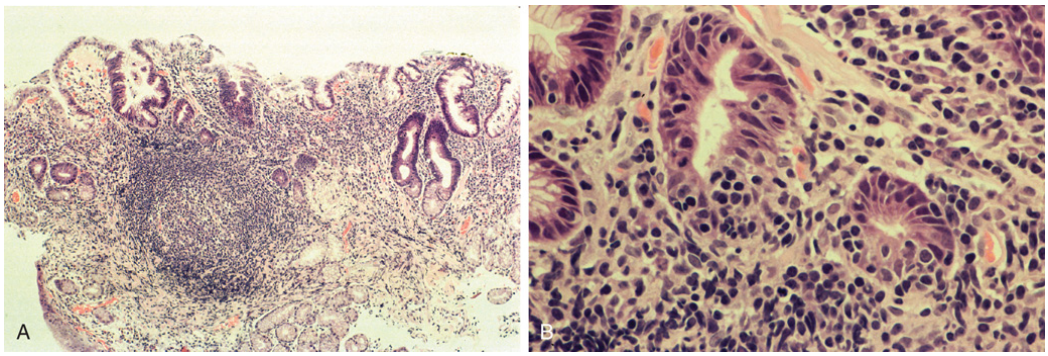

FIGURE 18-9 **A,** *Helicobacter pylori* gastritis with a prominent follicle adjacent to gastric glands. **B,** High magnification of gastric glands adjacent to the follicle shows infiltration of glandular epithelium by small lymphocytes, mimicking a lymphoepithelial lesion.

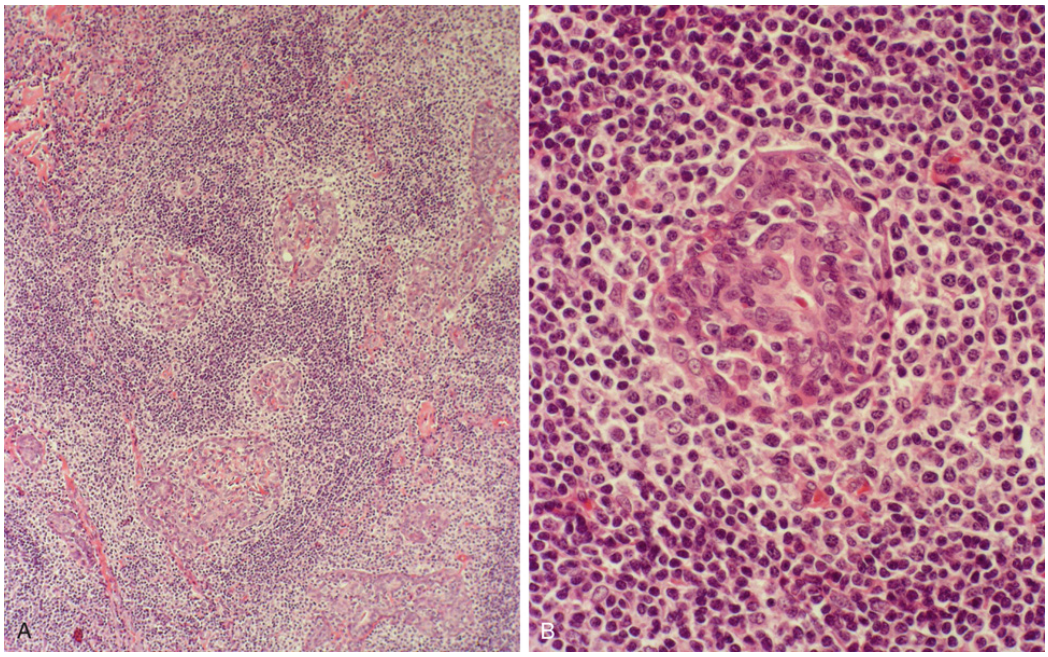

FIGURE 18-10 An early MALT lymphoma of the parotid gland evolving from lymphoepithelial sialadenitis.A, Lymphoma cells form halos around lymphoepithelial lesions and begin to become confluent. **B,** High magnification of the lymphoma cells constituting the halos.

MALT Versus Other Small B-Cell Lymphomas

Because of differences in clinical behavior and management, it is important to differentiate MALT lymphoma from the other small B-cell lymphomas that may present in or involve extranodal sites (**Table 18-4**). These include mantle cell lymphoma, chronic lymphocytic leukemia/small lymphocytic lymphoma, and FL. The need to distinguish between MALT lymphoma and lymphoplasmacytic lymphoma involving extranodal sites can also arise.

Table 18-4

CB, Centroblast; *CC,* centrocyte; *CCL,* centrocyte-like; *CLL,* chronic lymphocytic leukemia; *Ig,* immunoglobulin; *LEL,* lymphoepithelial lesion; *MALT,* mucosa-associated lymphoid tissue.

* Table highlights typical immunophenotypic features; exceptions may occur in some cases.

The cytologic features of mantle cell lymphoma can closely simulate those of MALT lymphoma, to the extent that occasional lymphoepithelial lesions may be present. However, the absence of transformed lymphoid cells, together with expression of CD5, cyclin D1, a consequence of the t(11;14)(q13;q32) *CCND1*::*IGH* translocation, and SOX11 can distinguish mantle cell lymphoma.[192] Chronic lymphocytic leukemia/small lymphocytic lymphoma is characterized by small, round lymphocytes, usually with peripheral blood lymphocytosis and often with proliferation centers, although these may be difficult to appreciate in extranodal sites. Expression of CD5, CD23, and LEF1, without cyclin D1, provides further distinction from MALT lymphoma.[193] FL, which may arise extranodally, can be difficult to distinguish from MALT lymphoma with prominent follicular colonization. The transformed MALT lymphoma cells within the follicles may closely resemble centroblasts, but are typically negative for CD10 and BCL6, in contrast to the cells of FL, which usually express both antigens, both within and between follicles. Assessment of these antigens, together with stains for follicular dendritic cells such as CD21 or CD23, is useful. Evaluation of other germinal center–associated markers, such as LMO2, HGAL, GCET and MEF2B, and stains for IRTA1 and MNDA, which show

selective expression in marginal zone lymphomas, may provide additional help in selected cases.[145,146,194,195] Cytogenetic and molecular genetic analysis to detect *MALT1* and *BCL2* rearrangements is also useful. Finally, MALT lymphoma with plasmacytic differentiation can be distinguished from lymphoplasmacytic lymphoma if the characteristic architecture is identified and marginal zone/monocytoid B cells are present. In cases lacking such features, the clinical picture—evidence of bone marrow involvement or a paraprotein—may aid in the diagnosis. Furthermore, PCR studies for the *MYD88* L265P point mutation may be helpful, as this abnormality has been demonstrated in the vast majority of lymphoplasmacytic lymphomas, but has been reported in only a minority of cases diagnosed as extranodal MALT lymphoma.[196,197]

Pearls and Pitfalls

- Antigen drive plays a key role in most MALT lymphomas, although in some cases the initiating antigen has not been identified.
- PCR studies for IGH and IGK rearrangements may be useful for the distinction of reactive hyperplasia from MALT lymphoma; however, both false-positive and false-negative results may occur.
- Demonstration of light chain restriction in a MALT lesion is useful in the distinction of acquired MALT and MALT lymphoma.

- Rare atypical marginal zone hyperplasias, primarily arising at native MALT sites in children, may show lambda light chain restriction and should not be diagnosed as MALT lymphomas in the absence of definitive B-cell clonality by molecular methods.
- Gastric MALT lymphomas with a t(1;14) *BCL10*::*IGH* or t(11;18) *BIRC3*::*MALT1* translocation fail to respond to antibiotics as the sole therapeutic modality.
- MALT lymphomas may disseminate late to lymph nodes, and in many cases the distinction between primary and secondary marginal zone lymphomas in lymph nodes is difficult. A careful clinical history is key.

EBV-POSITIVE MUCOCUTANEOUS ULCER AND OTHER CUTANEOUS IMMUNODEFICIENCY-ASSOCIATED B-CELL LYMPHPROLIFERATIVE DISORDERS

Primary cutaneous B-cell lymphomas (CBCLs) are a heterogeneous group of B-cell lymphomas that present in the skin without evidence of extracutaneous disease at the time of diagnosis.[1] CBCLs are much less common than primary cutaneous T-cell lymphomas (CTCLs). In Western countries, CBCLs constitute approximately 25% of all primary cutaneous lymphomas, and their overall annual incidence rate is estimated at 3.1 cases per 1 million individuals.[1,2] However, CBCL appears to be much less common in Asian countries.[3,4] It is important to differentiate CBCLs from systemic B-cell lymphomas secondarily involving the skin. Compared with their nodal counterparts, CBCLs often have a completely different clinical behavior and prognosis and require a different therapeutic approach; they are therefore classified separately. For this purpose, in every patient with a diagnosis of B-cell lymphoma in the skin, careful physical examination, routine blood examination, and appropriate imaging studies (computed tomography [CT] or positron emission tomography [PET]-CT) are required to exclude secondary cutaneous

disease. Bone marrow examination is mandatory in high-grade malignant CBCL, but it is optional in low-grade malignant CBCL.[5,6]

Historical Background

The history of CBCL dates back to the 1980s after the introduction of immunohistochemistry in the diagnosis and classification of malignant lymphomas.[7] At that time, it was still firmly believed that skin localizations of malignant lymphomas other than mycosis fungoides (MF) and Sézary syndrome (SS) were manifestations of a systemic lymphoma, even if staging procedures failed to demonstrate extracutaneous disease, and patients were treated accordingly.

A major advantage of cutaneous lymphomas compared with malignant lymphomas arising at other sites is that the former can be seen by the naked eye and biopsied easily. This offers the unique opportunity to correlate the clinical appearance and clinical behavior with the histologic, immunophenotypic, and genetic features of these conditions. Clinicopathologic correlation is often essential to make a definite diagnosis. Such an approach contributed significantly to the diagnosis and classification of primary cutaneous lymphomas and resulted in the recognition of new types of CTCL and CBCL. These new types of CTCL and CBCL were found to have highly characteristic clinical and histologic features and often had a completely different clinical behavior and prognosis than morphologically similar nodal lymphomas and required a different type of treatment.[7] Primary cutaneous lymphomas were therefore included as distinct entities in lymphoma classifications, initially in a separate classification for primary cutaneous lymphomas (EORTC classification of cutaneous lymphomas),[8] but after the WHO-EORTC

consensus classification in 2005,[9] they were incorporated in the 4th edition of the WHO classification of hematopoietic neoplasms and its updates, including the 2022 International Consensus Classification (ICC).[10-12] In the 2018 update of the WHO-EORTC classification for primary cutaneous lymphomas, the 2022 ICC, and the 5th edition of the WHO classification for hematolymphoid tumors, three main types of CBCL are recognized: primary cutaneous marginal zone lymphoma (PCMZL) considered a lymphoproliferative disorder in the 2022 ICC (PCMZLPD), primary cutaneous follicle center lymphoma (PCFCL), and primary cutaneous diffuse large B-cell lymphoma, leg type (PCDLBCL, LT).[1,11,12] In addition, Epstein-Barr virus (EBV)-positive mucocutaneous ulcer has been included as a distinct entity. Intravascular large B-cell lymphoma and B-lymphoblastic lymphoma can also manifest in the skin first, but these conditions are not considered "primary cutaneous lymphoma." They are considered manifestations of systemic disease and should be treated accordingly, even in those rare cases where initial staging is negative.

Primary Cutaneous MARGINAL ZONE Lymphoproliferative Disorder

Definition

PCMZLPD is an indolent lymphoma composed of small B cells, plasma cells, and a variable number of reactive T cells. It includes cases previously designated as primary cutaneous immunocytoma,[13] cutaneous follicular lymphoid hyperplasia with monotypic plasma cells,[14] and primary cutaneous plasmacytoma without underlying multiple myeloma (extramedullary plasmacytoma of the skin).[15] In

the 4th edition of the WHO classification and revised 4th edition, PCMZLPD was not yet listed separately but included in the broad group of extranodal marginal zone lymphomas of mucosa-associated lymphoid tissue (MALT lymphoma). However, in the 2022 ICC and 5th edition of the WHO classification, PCMZLPD is recognized as a distinct entity, separate from other MALT lymphomas, although still termed PCMZL in the latter classification.[11,12] The 2022 ICC introduced the term lymphoproliferative disorder (LPD) for this entity rather than *lymphoma* because of the extremely indolent clinical behavior with disease-specific survival rates approaching 100%.[12]

Synonyms and Related Terms

WHO Revised 4th edition: Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)

WHO Proposed 5th edition: Primary cutaneous marginal zone lymphoma

PCMZLPD was not segregated from other MALT lymphomas in the WHO revised 4th edition.

Epidemiology

PCMZLPDs make up about 9% of all cutaneous lymphomas and about 40% of primary CBCLs.[1] They most commonly affect (young) adults, and a male predominance has been reported.[16-18]

Etiology

PCMZLPDs have been described in relation to tattoo pigments, tick bites, and antigen injection, suggesting they may develop from

chronic antigenic stimulation by intradermally applied antigens.[19,20] However, in most cases, the cause is unknown. An association with *Borrelia burgdorferi* infection has been reported in a minority of European cases of PCMZLPD, but not in cases from Asia or the United States.[21-24] One report described a high incidence of gastrointestinal disorders and autoimmune diseases in patients with PCMZLPD.[25]

Clinical Features

PCMZLPD presents with red-to-violaceous papules, plaques, or nodules localized preferentially on the trunk and upper arms (**Fig. 19-1A**). In contrast to PCFCL, patients more often present with multifocal skin lesions (**Table 19-1**). Ulceration is uncommon. Cutaneous relapses occur frequently, particularly in patients presenting with multifocal skin lesions.[18,26,27] However, extracutaneous dissemination is uncommon and is reported in only 4% to 8% of the patients.[16-18] Bone marrow involvement is exceedingly rare, and a bone marrow biopsy is therefore not required unless indicated by other staging procedures.[5,6]

Histopathology

These lymphomas show patchy, nodular, or diffuse dermal infiltrates with sparing of the epidermis (**Fig. 19-1B**). The infiltrates are composed of small B cells, plasma cells, often follicles with reactive germinal centers, and in most cases, an abundant T-cell infiltrate. Monotypic plasma cells are often located at the periphery of the infiltrates and in the subepidermal compartment.[13,28,29] Unlike marginal zone lymphoma (MZL) occurring at other sites, PCMZLPD

does not or rarely shows colonization of reactive germinal centers by neoplastic B cells, lymphoepithelial lesions, or transformation into a diffuse large B-cell lymphoma. Diffuse infiltrates of small B cells with a monocytoid appearance should raise suspicion of a systemic lymphoma. In rare cases, a pure population of neoplastic plasma cells, formerly classified as *primary cutaneous plasmacytoma,* can be observed. Reports suggest that amyloid light chain (AL) amyloidoma, which refers to cases showing amyloid deposits in combination with monotypic plasma cells, should be considered a rare variant of PCMZLPD.[30,31]

FIGURE 19-1 Primary cutaneous marginal zone lymphoproliferative disorder.**A,** Typical clinical presentation with multiple nodules on the back. **B,** Dense infiltrates throughout the dermis are shown. **C,** CD79a staining shows a predominance of B cells and reactive germinal centers. **D,** Monotypic immunoglobulin G, kappa-positive plasma cells in the superficial dermis (kappa staining). **E,** Negative staining for lambda light chains.

Immunophenotype

Tumor cells express CD20, CD79a, and BCL2, but are negative for CD5, CD10, and BCL6, which may be useful in distinction from PCFCL (**Table 19-2**).[32,33] Reactive germinal centers are typically positive for BCL6 and CD10 and negative for BCL2. Plasma cells express CD138, IRF4/MUM1, and CD79a, but generally not CD20, and show monotypic cytoplasmic immunoglobulin light chain expression on paraffin sections (**Fig. 19-1C–E**). In some cases, biclonal expression of kappa and lambda light chain–restricted B cells has been reported.[34,35] Studies describe the existence of two types of PCMZLPD.[36-38] Unlike most other MALT lymphomas, the vast majority of PCMZLPD expresses class-switched immunoglobulins, including immunoglobulin (Ig)G, IgA, and IgE; do not express the chemokine receptor CXCR3, which has been suggested to play a role in homing of the malignant B cells to mucosa-associated malignant tissue; and have a Th2 inflammatory background. These cases show a predominance of T cells and often

contain reactive follicles and only a small proportion of small B cells. PD-1 is expressed by variable numbers of T cells, and in some cases, these PD-1–positive T cells even form rosettes, considered characteristic of primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disorders (PCSM-TCLPDs).[38,39] As some cases of PCSM-TCLPD may contain monotypic plasma cells, differentiation between the two conditions is sometimes difficult.[38,39] Clusters of CD123-positive plasmacytoid dendritic cells are typically found in the periphery of the infiltrates.[40] IgG4 is expressed in up to 40% of PCMZLPD cases with plasmacytic differentiation, whereas IgG4 is rarely expressed in non-cutaneous MZL.[41,42] There is no evidence of systemic IgG4 disease in these cases, pointing to a localized immunologic IgG4-driven process. The second type, consisting of a small subset of (P)CMZLPD, shows large nodules or sheets of small B-cells, including monocytoid B cells, which express IgM and often CXCR3 and IRTA1.[43] These cases contain a much lower number of admixed T cells and are more likely have extracutaneous disease.[37]

Table 19-1

Table 19-2

Phenotypic markers refer to the neoplastic cells except in CLH where BCL6, CD10, and BCL2 refer to the reactive germinal centers.

CLH, Cutaneous lymphoid hyperplasia; *CLL/SLL,* chronic lymphocytic leukemia/small lymphocytic lymphoma; *PCFCL,* primary cutaneous follicle center lymphoma; *PCMZLPD,* primary cutaneous marginal zone lymphoproliferative disorder.

Genetic Features

Clonal rearrangements of the immunoglobulin heavy chain (IGH) gene are found in approximately 80% of cases. The presence of the t(14;18)(q32;q21) translocation involving the IGH gene on chromosome 14, the *MALT* gene on chromosome 18, and the t(3;14)(p14.1;q32) translocation involving the IGH and *FOXP1* genes has been reported in a proportion of PCMZLPDs.[44-46] In one of these studies, the t(14;18)(q32;q21) translocation was only found in cases with a (partly) monocytoid appearance, as often seen in MZL in other organs.[46] Other translocations observed in MALT lymphomas at other sites, such as t(11;18)(q21;q21) and t(1;14)(p22;q32), are not or rarely found in PCMZLPD.[24,46-48] Mutations in the *FAS* gene affecting the functionally relevant death domain of the apoptosis-regulating FAS/CD95 protein were found in more than 60% of PCMZLPD cases, a feature distinct from other MALT lymphomas.[49] Highly recurrent mutations were also found in *SLAMF1, SPEN,* and *NCOR2*.[49] *MYD88* L265P mutations have been identified in some cases of non-class-switched (IgM-positive) PCMZLPD, but not in common class-switched (IgG-positive) cases.[50]

Differential Diagnosis

The differential diagnosis of PCMZLPD includes cutaneous lymphoid hyperplasia (CLH) (pseudo–B-cell lymphoma; lymphocytoma cutis), PCFCL with a follicular growth pattern, skin localizations of systemic small B-cell lymphomas/leukemias, and primary cutaneous small/medium T cell lymphoproliferative disorder (PCSM-TCLPD).

Differentiation between the common class-switched form of PCMZLPD and CLH can be challenging. Apart from clinical and histologic similarities, clonal B-cell receptor rearrangements have not only been found in approximately 80% of PCMZLPDs, but also in a small subset of CLH.[19,20] Demonstration of monotypic plasma cells expressing either kappa or lambda light chain by immunohistochemistry or in situ hybridization on paraffin sections is generally used as a decisive criterion for PCMZLPD. However, monotypic plasma cells may be minimal, and when evaluating recurrent lesions, they can be undetectable in some of these lesions. The observation that both PCMZLPDs and CLH may develop from chronic stimulation by intradermally applied antigens (e.g., tattoo pigments, tick bites, and antigen injections) suggests they represent a continuous spectrum of cutaneous B-cell proliferations with a stepwise progression from a reactive to a neoplastic state.[19,20] These observations have also resulted in discussions about whether what has traditionally been considered PCMZL, or at least a major subset of those cases, should be considered a clonal lymphoproliferative disorder rather than an overt malignant lymphoma.[12,38,51] The ICC adopted this new terminology, although the proposed WHO 5th edition classification did not.

The clinical and histologic features of MZL arising at noncutaneous sites and involving the skin secondarily may resemble those of PCMZLPD. Histologic features suggesting secondary cutaneous involvement include the presence of a predominant B-cell infiltrate and expression of IgM by the neoplastic B cells.[37] Colonization of follicular structures by neoplastic marginal zone cells and the presence of lymphoepithelial lesions are common in MALT lymphomas at other sites but are rarely seen in PCMZLPD and should therefore raise suspicion of secondary cutaneous involvement. In particular in such cases, staging is necessary to rule out extracutaneous disease. Differentiation between PCMZLPD and skin localizations of other systemic small B-cell lymphomas (e.g., mantle cell lymphoma, chronic lymphocytic leukemia/small lymphocytic lymphoma) may sometimes be difficult based on histology alone.[52] Staining for CD5 and cyclin D1 may be useful to differentiate PCMZLPD (CD5 negative, cyclin D1 negative) from mantle cell lymphoma (CD5 positive, cyclin D1 positive) and skin localizations of chronic lymphocytic leukemia/small lymphocytic lymphoma (CD5 positive, cyclin D1 negative) (**Table 19-2**). In cases with a predominance of plasma cells, multiple myeloma should be excluded by appropriate staging, which should include a bone marrow biopsy and serum electrophoresis. Differentiation between PCMZLPD and PCFCL is discussed in this chapter's section on PCFCL.

PCMZLPD shows overlapping clinicopathologic features with PCSM-TCLPD.[39] Clinically, both conditions present with a solitary or multiple papules or plaques and show an indolent clinical course. Histologically, they both show polymorphous dermal infiltrates with

mixed populations of B cells and T cells. Some cases of PCSM-TCLPD may show monotypic plasma cells and clonal IGH gene rearrangements characteristic of PCMZLPD, and PCMZLPD often contains clusters or rosettes of CD279/PD-1–positive T-cells considered characteristic of PCSM-TCLPD.[39]

Prognosis and Predictive Factors

PCMZL has an indolent clinical course. The prognosis is excellent, with a 5-year disease-specific survival rate close to 100%.[16-18,27]

Therapy

After EORTC/ISCL consensus recommendations, patients with a solitary tumor can be treated with radiotherapy or surgical excision.[53] In patients with associated *B. burgdorferi* infection, systemic antibiotics should be tried before more aggressive therapies are used. For patients presenting with multifocal skin lesions, a wait-and-see strategy can be adopted. Symptomatic lesions can be treated with topical or intralesional steroids, intralesional interferon α or rituximab, or low-dose radiotherapy. Systemic multiagent chemotherapy is rarely needed and should be reserved for patients who develop extracutaneous disease.

Primary Cutaneous FOLLICLE CENTER Lymphoma

Definition

PCFCL is a tumor of neoplastic follicle center cells with a predominance of large centrocytes (large cleaved cells) admixed with variable numbers of centroblasts (large noncleaved/transformed

cells with prominent and, usually, paracentral nucleoli) that may display a follicular, a follicular and diffuse, or a diffuse growth pattern and generally presents on the head or trunk.[1,11] Lymphomas with a diffuse growth pattern and a monotonous proliferation of centroblasts and immunoblasts are, irrespective of site, excluded and classified as PCDLBCL, LT.

Epidemiology

PCFCLs make up about 10% of all cutaneous lymphomas and about 50% of primary CBCLs. They most commonly affect middle-aged adults, with a slight male predominance.[1,16,17]

Clinical Features

PCFCL has a characteristic clinical presentation, with solitary or grouped plaques and tumors preferentially located on the scalp and forehead or on the trunk, but uncommonly on the legs (**Fig. 19-2**; **Table 19-1**).[16,17,54] Particularly on the trunk, these tumors may be surrounded by erythematous papules and slightly indurated plaques, which may precede the development of tumorous lesions for months or even many years. In the past, PCFCL with such a typical presentation on the back was referred to as *reticulohistiocytoma of the dorsum* or *Crosti's lymphoma*.[55] Presentation with multifocal skin lesions is observed in approximately 15% of patients but is not associated with a poor prognosis.[16,17,56,57] If left untreated, the skin lesions gradually increase in size over years, but dissemination to extracutaneous sites is uncommon.[16,17]

Histopathology

PCFCL shows perivascular and periadnexal, nodular or diffuse infiltrates with almost constant sparing of the epidermis. The infiltrates may show a follicular, a follicular and diffuse, or a diffuse growth pattern. Cases with a follicular growth pattern show nodular infiltrates throughout the entire dermis, often extending into the subcutaneous fat (**Fig. 19-3**). In contrast to reactive follicles in CLHs, the neoplastic follicles in PCFCLs are ill-defined, show a monotonous infiltration of generally medium-sized to large centrocytes enmeshed in a network of CD21-positive follicular dendritic cells, lack tingible body macrophages, generally have a reduced or absent mantle zone, and show a variably high proliferation rate with lack of polarization (**Fig. 19-3B**).[58,59] Reactive T cells may be numerous, and a stromal component is usually present. Cases with a diffuse growth pattern are characterized by a proliferation of medium-sized to large centrocytes, part of which may have a multilobated or spindle-shaped appearance, and variable numbers of admixed centroblasts (**Fig. 19-4A**). In rare cases, a predominance of centrocytes with a spindle-shaped appearance can be present (**Fig. 19-5**).[60-62]

FIGURE 19-2 Primary cutaneous follicle center lymphoma.Characteristic clinical presentation with localized skin lesions **(A)** on the back (Crosti's lymphoma) and **(B)** on the scalp.

Immunophenotype

The neoplastic cells express the B-cell–associated antigens CD20 and CD79a but are usually Ig negative. PCFCL consistently expresses BCL6, whereas CD10 is often positive in cases with a follicular growth pattern and generally negative in cases with a diffuse growth pattern (**Fig. 19-4B**).[17,32,33,63-65] Unlike nodal and secondary cutaneous follicular lymphomas, most PCFCLs do not express BCL2 protein or show faint BCL2 staining in a minority of neoplastic B cells (Figs. **19-3** and **19-5**).[17,54,58,66-68] However, other studies report BCL2 expression in a significant minority of PCFCL with a (partially) follicular growth pattern.[64,65,69] Notwithstanding, strong and diffuse expression of BCL6, BCL2, and CD10 by the neoplastic B cells should always raise suspicion of a systemic lymphoma secondarily involving the skin (**Table 19-1**). Staining for IRF4/MUM1, FOXP1, MYC, and IgM is negative in most cases, whereas staining for CD5 and CD43 is always negative.[17,54] In some cases with a diffuse growth pattern, foci of CD21-positive follicular

dendritic cells may still be present, though in other cases they may be completely lacking.

Genetic Features

Clonally rearranged immunoglobulin genes are present in most cases. Somatic hypermutation of variable heavy chain and light chain genes has been demonstrated, which further supports the follicle center cell origin of these lymphomas.[70,71] However, another study reported that PCFCL generally lacks ongoing somatic mutation and has low or absent activation-induced cytidine deaminase (AID), both unlike other follicular lymphomas.[72] In many studies, PCFCLs, including cases with a follicular growth pattern, do not or rarely show *BCL2* rearrangements, which is characteristically found in most nodal follicular lymphomas.[58,59,66-68,73] However, other studies report *BCL2* rearrangements using polymerase chain reaction (PCR) and/or fluorescence in situ hybridization (FISH) in about 10% of PCFCL with a follicular growth pattern and in some completely diffuse cases.[65,74-76] Gene expression studies demonstrated that PCFCL has a gene expression profile of germinal-center B-cell (GCB)–type DLBCL.[62,77] Genotypic studies found amplifications of the *REL* gene (63% of cases), as seen in GCB-type DLBCL, deletion of 14q32.33 containing the IGH gene locus (68% of cases), which may account for the lack of surface Ig in cases of PCFCL, and aberrant somatic hypermutation of certain proto-oncogenes.[78,79] Genes frequently mutated in follicular lymphomas in lymph nodes (e.g., *CREBBP, KTM2D* and *BCL2*) are significantly less commonly mutated in PCFCL.[80,81] Similar to classic follicular lymphomas, but in contrast to PCDLBCL, LT, B-cell receptor genes

in PCFCL appear to acquire N-linked glycosylation motifs, although they are mostly at different positions than in other follicular lymphomas.[72] In contrast to PCDLBCL, LT, *MYD88* L265P mutations and inactivation of *CDKN2A* and *CDKN2B* gene loci on chromosome 9p21.3 by deletion or promotor hypermethylation are not or rarely found in PCFCL.[78,82]

Differential Diagnosis

PCFCL with a follicular growth pattern should be differentiated from CLH (pseudo–B-cell lymphoma), PCMZLPD, and systemic follicular lymphomas with secondary cutaneous involvement. In contrast to reactive follicles in pseudo–B-cell lymphomas and PCMZLPDs, neoplastic follicles are ill-defined and show a reduced or absent mantle zone, no or few tingible body macrophages, and a monotonous population of medium-sized to large centrocytes with variable numbers of admixed centroblasts.[58,59] However, distinction between reactive and neoplastic follicles can sometimes be difficult. The presence of clusters of CD10-positive and/or BCL6-positive B cells outside the neoplastic follicles strongly suggests a diagnosis of PCFCL. Demonstration of B-cell clonality supports a diagnosis of CBCL but is by itself insufficient to make a definitive diagnosis. Differentiation between PCFCL and PCMZLPD is generally not difficult and is based on a different clinical presentation and a different morphology and phenotype of the neoplastic B cells (**Table 19-2**). PCFCL is characterized by the presence of large centrocytes with a BCL6-positive, commonly BCL2-negative, and CD10-positive or CD10-negative phenotype, whereas the neoplastic cells in PCMZLPD have a BCL6-negative, BCL2-positive, and CD10-negative

phenotype.[32,33] Moreover, monotypic light chain expression by lymphoplasmacytoid and plasma cells is a hallmark of PCMZLPD and is rarely observed in PCFCL. Distinction between rare cases of PCFCL showing a follicular growth pattern and strong expression of CD10 and BCL2, with or without *BCL2* rearrangement, and skin localizations of nodal follicular lymphoma can sometimes be impossible and can only be made after appropriate staging.[64]

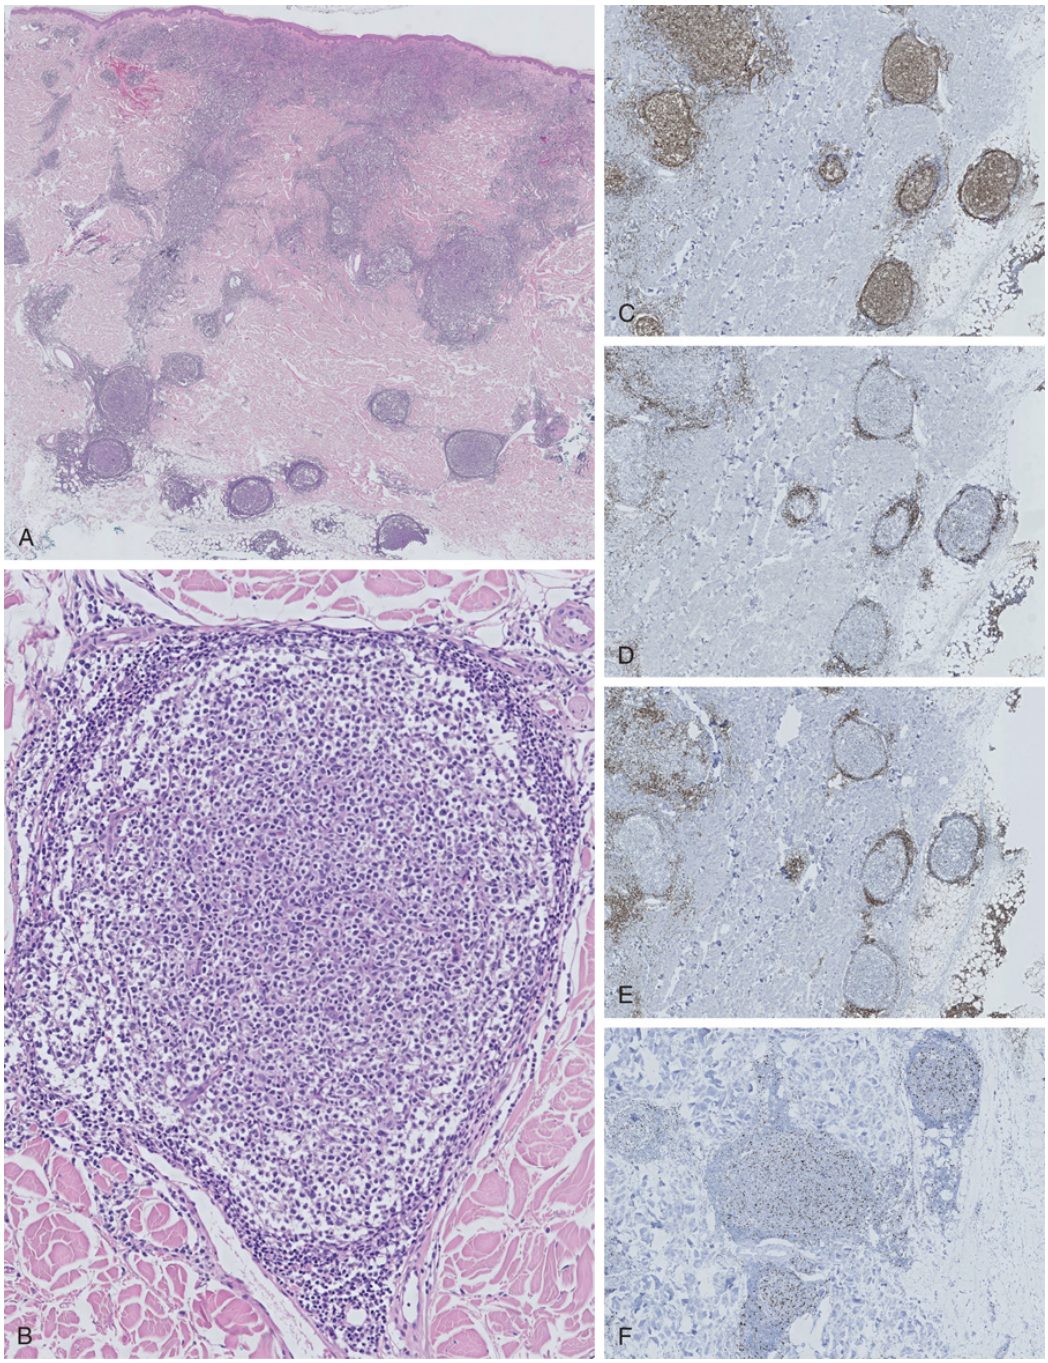

FIGURE 19-3 Primary cutaneous follicle center lymphoma, follicular and diffuse growth pattern.**A,** Histology of a skin tumor showing a diffuse infiltrate of neoplastic B cells in the superficial dermis and neoplastic follicles in the

deep dermis. **B,** Detail of neoplastic follicles showing a monotonous proliferation of B cells (no polarization), reduced mantle zone, and absence of tingible body macrophages. **C,** Positive staining of neoplastic B cells for CD79a. **D,** CD3-positive T cells at the periphery of the neoplastic follicles. **E,** BCL2 stains T cells, but not intrafollicular neoplastic B cells. **F,** Ki-67 staining shows only few proliferating cells in neoplastic follicles.

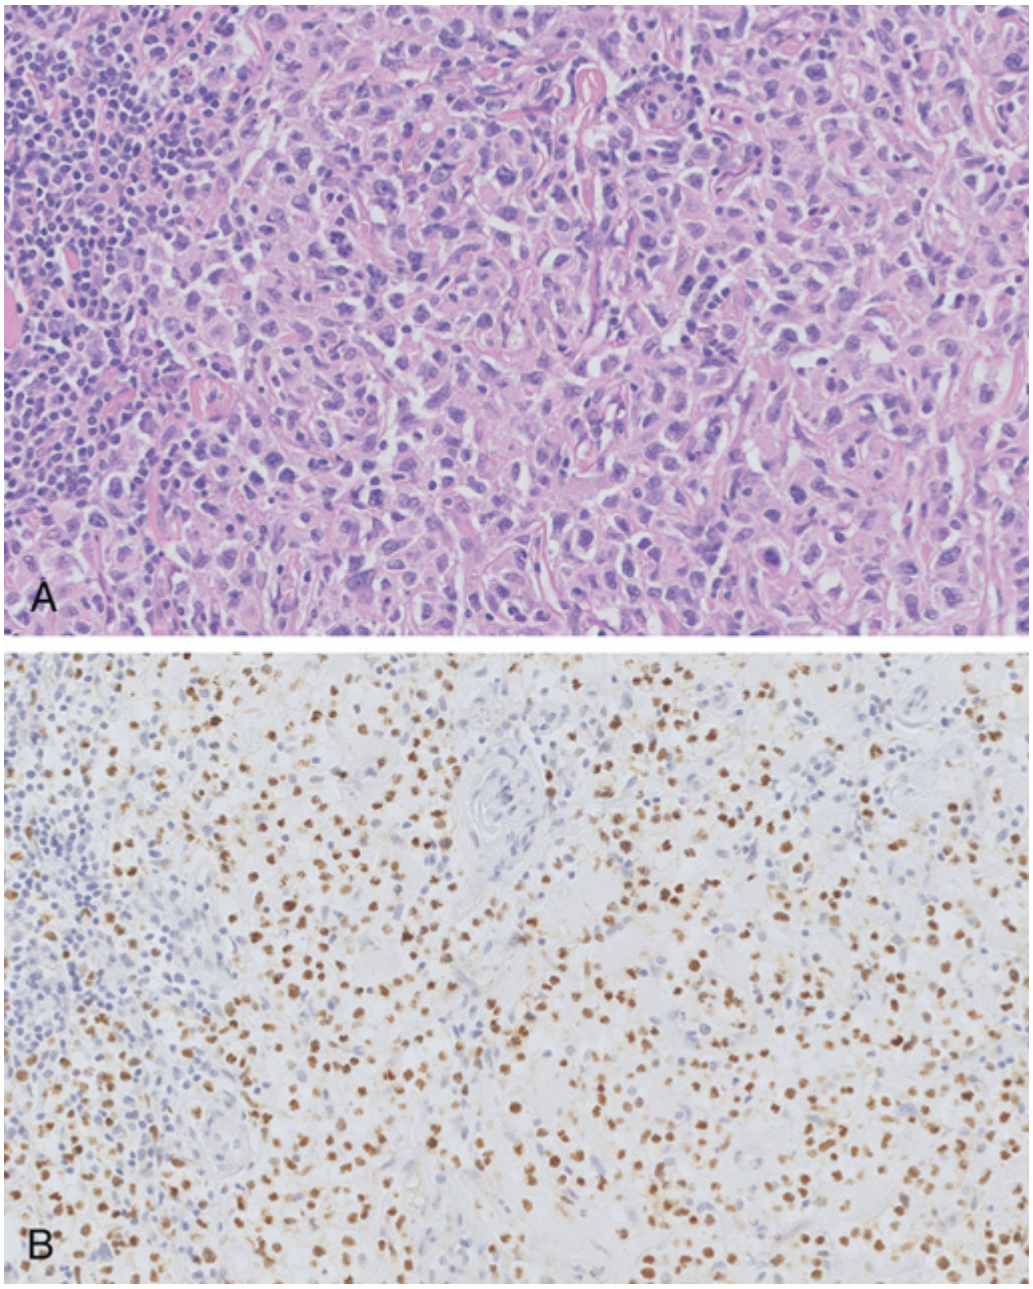

FIGURE 19-4 Primary cutaneous follicle center lymphoma, diffuse growth pattern.**A,** Diffuse infiltrate of large centrocytes (large, cleaved cells), partly with a multilobated appearance. **B,** BCL6 expression by neoplastic B cells.

PCFCL with a diffuse growth pattern, previously often classified as diffuse large B-cell lymphoma, should be differentiated from PCDLBCL, LT. Clinical, histologic, immunophenotypical, and genetic differences between the conditions are summarized in **Table 19-3** and mostly suffice to make a correct diagnosis.

Prognosis and Predictive Factors

PCFCLs have an indolent clinical course. Cutaneous relapses after initial treatment occur in approximately 30% of patients, whereas extracutaneous dissemination is reported in approximately 10% of patients.[16,17] PCFCLs have an excellent prognosis with a 5-year disease-specific survival rate of 95%, irrespective of the growth pattern (follicular, follicular and diffuse, or diffuse), the number of blast cells, the presence or absence of BCL2 expression or *BCL2* rearrangements, or the presence of either localized or generalized skin lesions.[1,16,17,83] Rare cases of PCFCL presenting on the leg are reported to have a poor prognosis, similar to that of patients with PCDLBCL, LT.[17,54]

Therapy

In patients with localized skin lesions, radiotherapy is the preferred mode of treatment.[53] Solitary lesions that are small and well-demarcated can be treated with surgical excision. Cutaneous relapses do not indicate progressive disease and can be treated with radiotherapy as well. For relapses, a palliative dose of 4 Gy can be used, which will result in effective local control in 90% of cases.[84] In patients with few scattered lesions, both low-dose radiotherapy and a wait-and-see policy with treatment of only symptomatic lesions can

be considered, similar to the recommendations for PCMZLPD. Systemic or intralesional administration of rituximab is a safe and effective treatment for patients with generalized skin lesions, but cutaneous relapses are frequently observed.[85,86] Multiagent chemotherapy (CHOP [cyclophosphamide, doxorubicin, vincristine, and prednisone] in combination with rituximab [R-CHOP]) should be reserved for patients who develop extracutaneous disease and only for exceptional patients with generalized skin lesions that do not respond to other treatment modalities. Patients with a PCFCL presenting on the leg(s) have a similar prognosis as those with PCDLBCL, LT and should be treated as such.[17,54]

Primary Cutaneous Diffuse Large B-Cell Lymphoma, Leg Type

Definition

PCDLBCL, LT is characterized by tumors with a predominance or confluent sheets of centroblasts and immunoblasts, most commonly arising on the legs. Uncommonly, skin lesions with a similar morphology and phenotype can arise at sites other than the legs. Initially, these lymphomas, classified as centroblastic and/or B-immunoblastic lymphomas according to the Kiel classification, were included in the group of PCFCLs and recognized as a subgroup with an inferior prognosis.[87] Because of their characteristic clinical presentation, morphology, immunophenotype, and clinical behavior that were all different from PCFCL with a diffuse proliferation of large centrocytes, these lymphomas were included as a separate entity in the EORTC classification and, later on, with slight

modifications, in the WHO-EORTC, WHO, and ICC classifications.[1,9-11,12]

Epidemiology

PCDLBCL, LTs account for about 4% of all cutaneous lymphomas and about 15% to 20% of primary CBCLs.[1] It typically occurs in elderly patients with a median age of around 75 years and is more frequent in women.[54,72]

Clinical Features

Patients present with generally rapidly growing red or bluish-red tumors on one or both (lower) legs or in approximately 20% at sites other than the legs (**Fig. 19-6A**).[17,54,88] In contrast to PCFCLs, these lymphomas more often disseminate to extracutaneous sites and have a poor prognosis (**Table 19-1**).[17,54,89]

Histopathology

These lymphomas show diffuse non-epidermotropic infiltrates, which often extend into the subcutaneous tissue. The infiltrates are composed of a monotonous population or confluent sheets of large B cells with round nuclei and prominent nucleoli; in general, a mixed population of centroblasts and immunoblasts is seen (**Fig. 19-6B**).[17,63,89] Mitotic figures are frequently observed. Small B cells and (remnants of) CD21-positive follicular dendritic cell networks are lacking, and reactive T cells are relatively few and often confined to perivascular areas.

Immunophenotype

The neoplastic cells express the B-cell–associated antigens CD20 and CD79a and, unlike PCFCLs, are strongly positive for BCL2, IRF4/MUM1, FOXP1, MYC, and cytoplasmic IgM with monotypic light chain expression and co-expression of IgD in 50% of cases (**Fig. 19-6C–E**). BCL6 is expressed in most cases, whereas CD10 staining is generally absent.[17,63,90-92] However, in approximately 10% of cases, deviations of this typical immunophenotype (e.g., BCL2 or IRF4/MUM1 negativity and weak CD10 positivity) may be found. Such cases might still be diagnosed as PCDLBCL, LT if the other diagnostic features of the entity are present (**Table 19-3**).[17,54,93] Ki-67 generally stains more than 75% of the neoplastic cells.

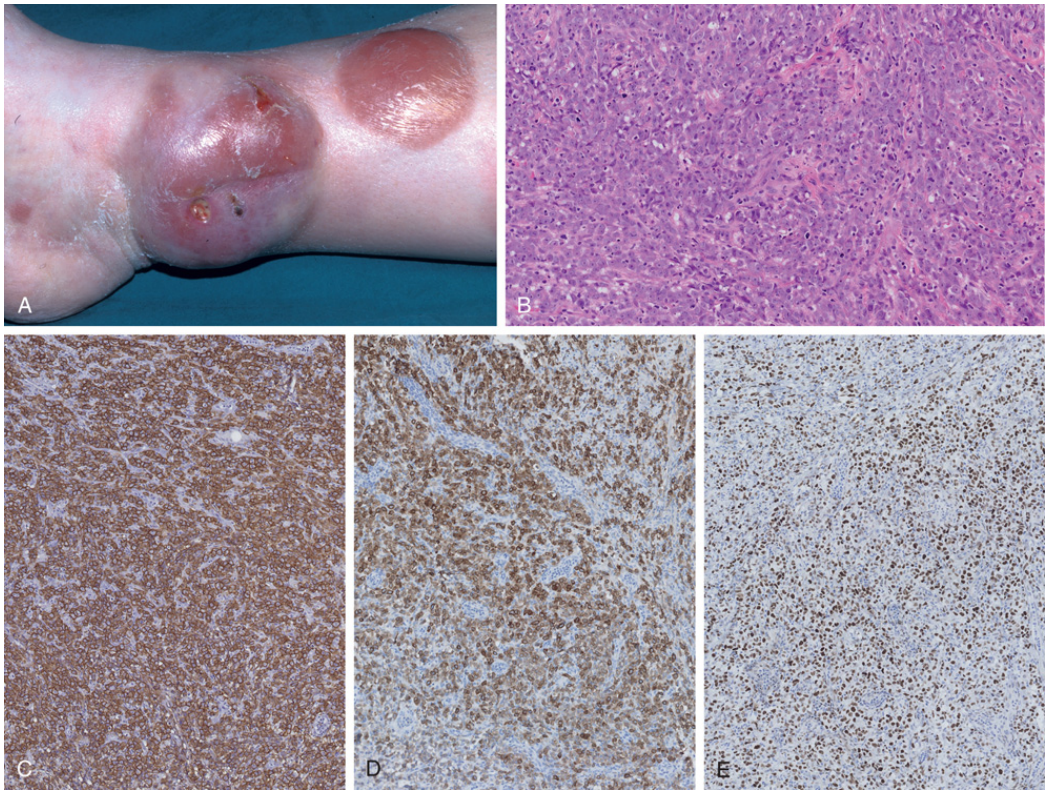

FIGURE 19-6 Primary cutaneous diffuse large B-cell lymphoma, leg type.**A,** Clinical presentation with large tumors on the right lower leg. **B,** Diffuse proliferation of centroblasts and immunoblasts. Tumor cells show strong reactivity for CD20 **(C),** immunoglobulin M **(D),** and MYC **(E).**

Genetic Features

Genetic studies showed marked differences between PCDLBCL, LT and PCFCL with a diffuse proliferation of large B cells.[62,77,82] Chromosomal translocations involving *BCL6, MYC,* and IGH are frequently found in PCDLBCL, LT, but *BCL2* translocations are exceptional.[92,94-96] The strong BCL2 expression in PCDLBCL, LT

may be explained by high-level amplifications of the *BCL2* gene reported in 67% of cases.[78] Loss of *CDKN2A* and *CDKN2B* either by gene deletion or promoter methylation has been reported in 67% to 75% of cases and correlates with a poor prognosis.[78,97,98] PCDLBCL, LTs show highly recurrent *MYD88* L265P mutations (70%–75%), frequent mutations in *PIM1,* and mutations in other genes affecting the NF-κB and B-cell receptor signaling pathways, including *CD79B, CARD11,* and *TNFAIP3/A20*.[96,99,100] Genetic alterations in immune evasion pathways, such as deletions of the *MHCI/II* loci and the MHC regulator *CIITA* and translocations of the *PD-L1/2* loci have been described.[98,101] The mutational profile of PCDLBCL, LT resembles that of lymphomas arising in immune-privileged sites, as in primary DLBCL of the central nervous system (CNS) and testis[93,96,98,101] and DLBCL of the MCD/C5 type.[102,103]

Differential Diagnosis

PCDLBCL, LT should be differentiated from PCFCL with a diffuse proliferation of large centrocytes, systemic DLBCL secondarily involving the skin, and several other specific types of large B-cell lymphomas. Differentiation between PCDLBCL, LT and PCFCL is extremely important, because the conditions have different prognoses and require different therapeutic approaches. Distinguishing features are summarized in **Table 19-3**. In rare cases that cannot be classified as either PCDLBCL, LT or PCFCL, PCDLBCL, NOS might be diagnosed, which should, however, not be considered as a specific entity. Distinction between PCDLBCL, LT and systemic DLBCL with secondary cutaneous involvement requires adequate staging. Plasmablastic lymphomas are seen almost

exclusively in the setting of HIV infection or other immune deficiencies, including in the elderly with immune senescence.[104-106] Some of these cases have only skin lesions at presentation.[107] Rare cases of primary cutaneous T-cell/histiocyte–rich B-cell lymphoma, characterized by the presence of large scattered B cells on a background of numerous reactive T cells and histiocytes, have been reported.[108,109] Clinically, these lymphomas commonly present with a solitary skin tumor on the head or on the trunk and show similarities with the group of PCFCLs. Unlike their nodal counterparts, they appear to have an excellent prognosis.[110]

Other specific types of DLBCL that can present with only skin lesions, such as intravascular large B-cell lymphoma, immunodeficiency-related B-cell neoplasms, and B-lymphoblastic lymphoma (B-LBL), are discussed later in this chapter.

Prognosis, Predictive Factors, and Treatment

These lymphomas have a much more aggressive clinical behavior and poorer prognosis than PCFCL and PCMZLPD. Previous studies reported a disease-specific 5-year survival rate of approximately 50%.[17,83,89] More recent studies reported a significantly better clinical outcome for patients treated with a combination of multiagent chemotherapy (CHOP or CHOP-like) and rituximab than for patients treated with multiagent chemotherapy regimens alone.[88,111] The presence of multiple skin lesions at diagnosis, inactivation of *CDKN2A* either by deletion or hypermethylation, and presence of *MYC* translocations have been reported to be associated with an inferior prognosis.[78,83,92,95,112]

Intravascular Large B-Cell Lymphoma

Intravascular large B-cell lymphoma is a large B-cell lymphoma, defined by an accumulation of large neoplastic B cells within blood vessels. These lymphomas preferentially affect the CNS, lungs, and skin and are generally associated with a poor prognosis. Patients often have widely disseminated disease, but cases with only skin involvement may occur. This so-called “cutaneous variant” predominantly affects females and is more frequent in the Western world.[113] Clinically, patients may present with violaceous patches and plaques or telangiectatic skin lesions, usually on the (lower) legs or the trunk (**Fig. 19-7A**).[113] Patients presenting with only skin lesions appear to have a significantly better survival rate than patients with other clinical presentations.[113] In rare cases, intravascular B-cell lymphomas develop within the capillaries of cutaneous hemangiomas.[114,115] Histologically, blood vessels in the dermis and subcutis are filled and often dilated by a proliferation of large neoplastic B cells (**Fig. 19-7B**). The tumor cells express the B-cell–associated antigens, BCL2, IRF4/MUM1, IgM, and MYC; CD5 and PD-L1 (CD274) expression is seen in about half of the cases.[116-118] Tumor cells may cause vascular occlusion of venules, capillaries, and arterioles. In some cases, small numbers of tumor cells can also be observed around blood vessels. These lymphomas show recurrent mutations in *MYD88* L265P and *CD79B* Y196 and rearrangements of *PD-L1* and *PD-L2* genes, similar to those observed in PCDLBCL, LT and lymphomas arising in immune-privileged sites such as primary DLBCL of the CNS and testis.[117-119] Multiagent chemotherapy in combination with rituximab is the preferred mode of treatment, also in patients presenting with skin-limited disease.[120,121]

B-Lymphoblastic Lymphoma

B-LBL particularly affects children and young adults and often involves extracutaneous sites, most often the skin. Characteristically, patients present with a solitary tumor in the head and neck region, which can be the only manifestation of the disease.[122-125] Histologically, they show a diffuse monotonous infiltrate of medium-sized blast cells with often round nuclei, finely dispersed chromatin, inconspicuous nucleoli, and scant cytoplasm. A starry-sky pattern may be present. The neoplastic cells usually express CD79a, PAX5, CD10, and TdT, whereas CD20 expression may be weak or absent. CD99 is expressed in a proportion of cases. Patients should be treated with aggressive multiagent chemotherapy analogous to that designed for B-acute lymphoblastic leukemia, even when presenting with a solitary skin tumor. With this approach, the prognosis is often good.[126]

Ebv-Positive Mucocutaneous Ulcer and Other Cutaneous Immunodeficiency-Associated B-Cell LymphOproliferative Disorders

EBV-positive mucocutaneous ulcer (EBVMCU) is defined as a solitary, sharply demarcated ulcerating lesion involving the skin, oropharyngeal mucosa, or gastrointestinal tract in patients with age-related or iatrogenic immunosuppression (e.g., methotrexate [MTX], azathioprine, cyclosporine, TNF inhibitors).[1,11,12] Histologically, the lesions contain large Hodgkin-like EBV-positive B cells on a mixed inflammatory background. These large, transformed cells are PAX5

positive, show variable expression of CD20, display a non–germinal-center phenotype (IRF4/MUM1+, CD10–, BCL6–), and typically express CD30 with co-expression of CD15 in almost half of the cases.[127] EBVMCU usually runs a self-limited, indolent course. In iatrogenic cases, reduction of immunosuppressive therapy without additional chemotherapy or radiotherapy may result in complete remission.[127]

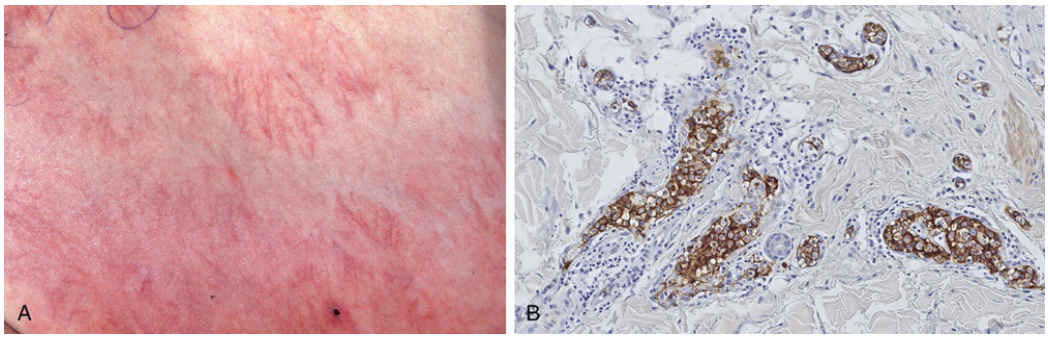

FIGURE 19-7 Intravascular large B-cell lymphoma.**A,** Clinical presentation with telangiectatic lesions on the trunk and legs. **B,** Intravascular population of CD20-positive large neoplastic B cells.

Apart from EBVMCU, there are other cutaneous manifestations of B-cell LPD occurring in the setting of iatrogenic immunosuppression: skin lesions may be EBV positive or negative and both can be solitary or generalized, with or without ulceration.[128] MTX-associated B-cell LPD usually shows the histology of DLBCL or has Hodgkin-like features. The latter is particularly seen in EBV-positive cases, which account for 40% to 50% of all cases. Recognition of these iatrogenic immunodeficiency-

associated lesions is important, as in all cases reduction or cessation of immunosuppressive treatment may result in (complete) remissions and should be attempted before more aggressive therapy is considered.[128,129]

Other EBV-positive conditions, such as EBV-positive DLBCL of the elderly and lymphomatoid granulomatosis, can occasionally present in the skin but are generally a manifestation of systemic disease (see **Chapter 28**).[130-132]

Pearls and Pitfalls

- Analogous to the term *CTCL* for primary cutaneous T-cell lymphomas, the term *CBCL* is preferably used only for B-cell lymphomas that present in the skin without evidence of extracutaneous disease at the time of diagnosis (primary CBCL). It is important to differentiate these CBCLs from systemic B-cell lymphomas secondarily involving the skin.
- Although histologic features may suggest a diagnosis of CBCL, a definitive diagnosis of CBCL can only be made if extracutaneous disease has been ruled out by adequate staging procedures.
- The localization of the presenting skin lesions in CBCL provides important diagnostic information: PCFCL preferentially presents with localized skin lesions on the head (mainly the scalp) or trunk, PCMZLPD on the trunk and/or upper arms, and PCDLBCL, LT on the (lower) legs.

- The presence of monotypic plasma cells at the periphery of dermal infiltrates and in the superficial dermis beneath the epidermis is a characteristic feature of PCMZLPD.
- The presence of a diffuse proliferation of small neoplastic B cells, expression of IgM, colonization of reactive germinal centers, and the presence of lymphoepithelial lesions are uncommon in PCMZLPD and should raise suspicion of secondary cutaneous involvement of systemic MZL.
- Distinction between low-grade malignant CBCL (i.e., PCMZLPD and PCFCL) and CLH (pseudo–B-cell lymphoma) may sometimes be extremely difficult. Demonstration of B-cell clonality supports a diagnosis of CBCL but is by itself insufficient evidence for a definitive diagnosis.
- The observation that both PCMZLPD and CLH (pseudo–B-cell lymphoma) may develop from chronic stimulation by intradermally applied antigens, such as tattoo pigments, tick bites, and antigen injections, suggests they represent a continuous spectrum of cutaneous B-cell proliferations.
- PCFCL may show a follicular, a follicular and diffuse, or a completely diffuse growth pattern, with a predominance of large centrocytes with varying proportions of admixed centroblasts (CBs). Neither the growth pattern nor the proportion of CBs affects prognosis.
- Presence of BCL2 expression or a *BCL2* translocation in a cutaneous B-cell lymphoma with a follicular growth pattern should raise the possibility of systemic follicular lymphoma with secondary cutaneous involvement but does not exclude a

diagnosis of PCFCL. In case of BCL2 expression or a *BCL2* translocation in PCFCL, prognosis is not affected.

- Distinction between PCFCL, diffuse type and PCDLBCL, LT is primarily based on morphologic criteria: PCFCL shows a predominance of large centrocytes, and PCDLBCL, LT is composed of centroblasts and immunoblasts. Additional immunophenotypic criteria include strong expression of BCL2, IRF4/MUM1, MYC, and cytoplasmic IgM, which is observed in most cases of PCDLBCL, LT but uncommon in PCFCL.
- The mutational profile of PCDLBCL, LT resembles that of B-cell lymphomas arising in immune-privileged sites, such as primary DLBCL of the CNS and testis, and shares similarities with the genetic signatures described in MCD/C5 DLBCL.
- In cases of cutaneous DLBCL with polymorphous or Hodgkin-like B cells, additional CD30 staining and in situ hybridization for EBV (EBER) should be performed and a diagnosis of immunodeficiency-associated lymphoproliferative disorder should be considered.
- B-lymphoblastic lymphoma sometimes presents with a solitary skin tumor in the head and neck region as the only manifestation of the disease. These patients should be treated with aggressive multiagent chemotherapy designed for B-acute lymphoblastic leukemia and may have a good prognosis.

Splenic Marginal Zone Lymphoma

Definition

Nodal marginal zone lymphoma (NMZL) is a primary nodal B-cell neoplasm derived from post–germinal-center B cells. This lymphoma shares morphologic and immunophenotypic similarities with other marginal zone lymphomas, particularly extranodal marginal zone lymphoma (EMZL) of mucosa-associated lymphoid

tissue (MALT) type and splenic marginal zone lymphoma (SMZL). Thus, secondary lymph node involvement by EMZL and SMZL should be excluded to establish the diagnosis with certainty. NMZL may show some evidence of plasmacytic differentiation, but it is generally less than that seen in lymphoplasmacytic lymphoma (LPL), which is often included in the differential diagnosis.

Epidemiology, Etiology, and Cofactors

NMZL is a relatively uncommon lymphoma, accounting for 1.5% to 1.8% of all lymphoid neoplasms.[1,2] It is primarily a lymphoma of adults. The median age of patients is between 50 and 60 years, with a female predominance in some, but not all, series.[3-6] An association with hepatitis C infection has been suggested in some studies[6,7] but not in others.[3] These discrepant results may relate to overlap among a variety of B-cell neoplasms and different diagnostic criteria. The distinctions among NMZL, EMZL, and SMZL can be difficult, and hepatitis C has been linked to both EMZL and SMZL.[8-11] Alternatively, these differences could relate to different risk factors in different populations of patients or geographic regions.

Underlying autoimmune disease has been implicated in a variety of EMZLs, including Sjögren syndrome and Hashimoto's thyroiditis.[12] However, a history of autoimmune disease is lacking in most patients with NMZL. Nodal involvement may be prominent in many patients with salivary gland MALT lymphoma, with a predominance of monocytoid B cells.[13] Therefore, a careful clinical history is important in the evaluation of these cases. Both autoimmune hemolytic anemia and cryoglobulinemia have been reported in a subset of patients with NMZL.[3,14] However, the

incidence is much less than that seen with LPL. Molecular studies have identified a high incidence of mutations in *MYD88* at L265P in Waldenström macroglobulinemia and LPL but only rarely in NMZL, facilitating this distinction.[15,16]

Clinical Features

The majority of patients have generalized peripheral lymphadenopathy,[2,3,6] although two series found a higher proportion of localized stage I or stage II disease.[4,5,17] B symptoms are present in a minority.[18] Clinical evaluation should be undertaken to rule out secondary nodal involvement by EMZL or SMZL, given the significant overlap in the morphologic features in lymph nodes.[17] Most investigators require the absence of extranodal sites of disease (other than bone marrow, liver, or spleen) in making the diagnosis.[4] Similarly, patients presenting with marked splenomegaly and bone marrow involvement with only minimal lymphadenopathy most likely fall into the category of SMZL. These imprecise diagnostic criteria make it difficult to compare clinical features and outcomes.

Bone marrow involvement is relatively uncommon in most series, occurring in less than half of the patients.[6] Peripheral blood involvement is generally rare, and the presence of circulating cells should at least raise the suspicion of other forms of B-cell neoplasia, including SMZL and atypical chronic lymphocytic leukemia (CLL). According to the International Prognostic Index (IPI) or the modified Follicular Lymphoma IPI (FLIPI), most patients are in the low or low-intermediate risk groups.[6] Elevations in lactate dehydrogenase are common but are usually modest.[18]

Although plasmacytoid differentiation can be observed histologically, it is uncommon to find monoclonal gammopathy in the serum.[14] One exception was the French series reported by Traverse-Glehen and colleagues[3] in which 33% of patients had an M component or monoclonal spike. These distinctions may relate to differences in diagnostic criteria and the overlap between NMZL and LPL in tissue biopsies.

Morphology

Cytologic Features

The neoplastic cells in NMZL are heterogeneous in appearance and have been described as monocytoid, centrocyte-like, and plasmacytoid.[3,17] These smaller cells are usually admixed with a variable number of transformed cells or blasts. Monocytoid cells have round-to-irregular nuclei with condensed nuclear chromatin, inconspicuous nucleoli, and abundant pale cytoplasm with distinct cytoplasmic membranes (**Fig. 20-1**). A monocytoid appearance is even more pronounced with secondary lymph node involvement by MALT lymphoma (**Fig. 20-2**). This histologic pattern should prompt a clinical evaluation for EMZL either concurrently or in the possibly distant past. Late relapses of EMZL have been described, sometimes many years after the primary diagnosis.[12,17] Centrocyte-like cells can be numerous in some cases. These small to medium-sized cells have coarsely clumped chromatin, irregular nuclei, and sparse cytoplasm. Plasmacytoid cells exhibit varying degrees of plasmacytoid differentiation. They are often slightly larger than the other cell types present, with an ample rim of basophilic cytoplasm. The nuclear chromatin is generally more dispersed than that of

mature plasma cells, and small nucleoli may be present. Dutcher bodies may be seen but are generally less common than in LPL. Larger lymphoid cells or blasts, reminiscent of centroblasts, are present in variable proportions but should not constitute the majority of cells present. The overall impression is that of a heterogeneous population of cells that are medium in size, generally round but irregular, and lacking the monotony seen in some other B-cell lymphomas such as CLL or mantle cell lymphoma.

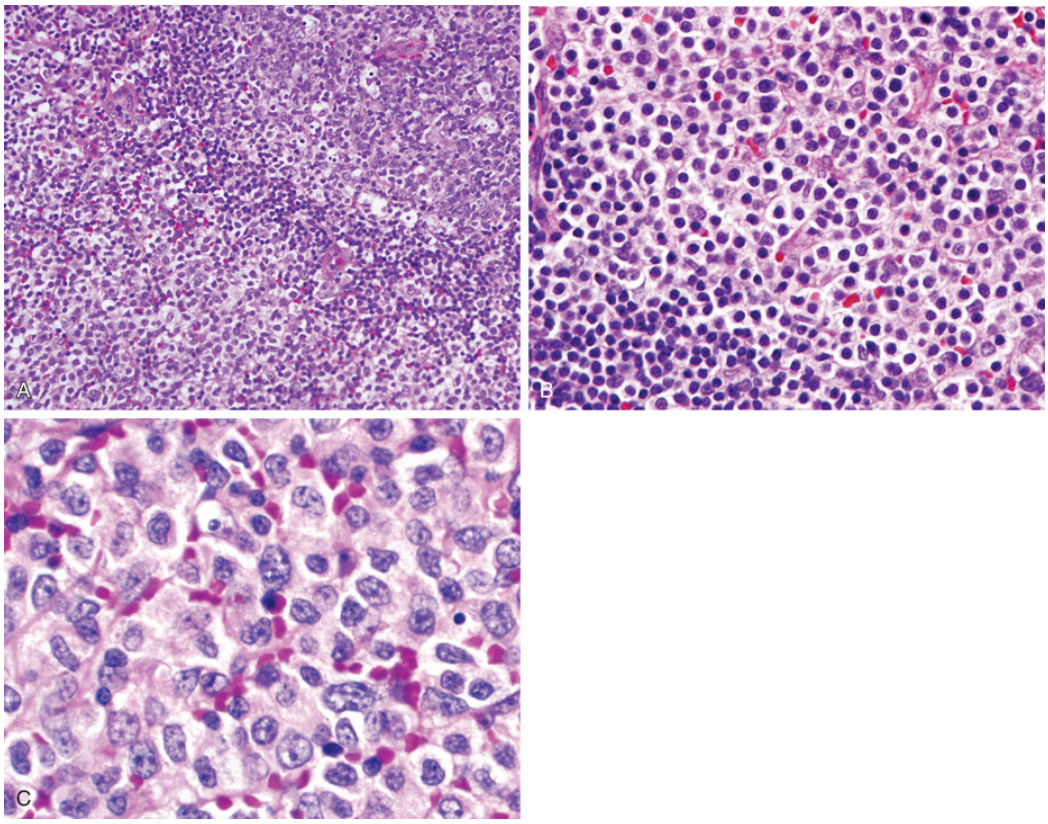

FIGURE 20-1 Nodal marginal zone lymphoma.**A,** In this case, reactive lymphoid follicles are well preserved, with an intact but attenuated lymphoid cuff. **B,** The neoplastic cells have abundant clear cytoplasm with a monocytoid appearance. **C,** The cells may have irregular nuclei, and admixed blasts are few.

Other inflammatory cells, particularly epithelioid histiocytes, may be present. However, well-formed granulomas are usually absent. Eosinophils may be noted, particularly in cases with plasmacytoid differentiation.[19]

Architectural Features

Varied architectural patterns are seen in NMZL.[3,17,20] In many instances, the infiltrate is diffuse.[20] However, often there is some semblance of residual follicles that can be expanded, regressed, or, in some instances, colonized by neoplastic cells. In most cases, the follicles are regressed, with absence of well-formed germinal centers. The regressed follicles may be better appreciated by stains for CD21, which highlight tight FDC meshworks (Figs. **20-2** and **20-3**).

The mantle cuff might be present but is usually attenuated. The neoplastic cells may be weakly immunoglobulin (Ig)D positive, but expression of IgD is dimmer than that seen in residual mantle cuffs.

Follicular colonization can be a prominent feature in NMZL, and extensive infiltration of residual follicles may impart a nodular or follicular growth pattern, mimicking follicular lymphoma (FL).[21] Follicular colonization also has been described in EMZL.[22] In some cases, the cytology of the cells within the colonized follicles may be different from that of the cells in the perifollicular zone and may show evidence of plasmacytoid differentiation. A higher proportion of blastic cells is sometimes noted within the colonized follicles. Finally, in some cases, the follicles contain a high content of small lymphocytes of T-cell lineage,[23] which may be associated with residual FDCs.

Cases that have been referred to as the pediatric variant of NMZL have distinctive features and will be discussed separately.[24]

Other Anatomic Sites

The appearance of NMZL in other anatomic sites is not well described. The incidence of bone marrow involvement has varied in different series, with most centers reporting a range of 20% to

40%.[18] Bone marrow infiltration generally consists of loose non-paratrabecular aggregates or, in some cases, interstitial infiltration.[25] One study also noted paratrabecular aggregates in some cases.[3] As previously noted, peripheral blood involvement is rare. Involvement of other extranodal sites usually leads to consideration of the diagnosis of EMZL.

Grading

There is no established grading system for NMZL, although considerable variation in the proportion of blastic cells or proliferating cells (as measured by Ki67) may be seen. In general, the proportion of blastic cells is less than 20% of the total cell population[14] (**Fig. 20-4**). Some authors have reported cases with foci of large cell transformation, but the clinical significance of these foci has not been shown.[1] In a subsequent study, the Lyon group noted that a number of cases contained more than 20% blastic cells and suggested that this feature might account for the more aggressive clinical course in that series.[3] However, the investigators were unable to relate outcome to the proportion of large cells or histologic progression. Specifically, there was no difference in survival between the groups with greater than 20% and less than 20% large cells. Nathwani and coworkers[2] reported a relatively high frequency (20%) of transformation to diffuse large B-cell lymphoma in NMZL, but the criteria for transformation were not delineated. Moreover, no difference in survival for those patients who had "transformed" was shown. One study from Japan found a poorer overall survival for cases of NMZL containing a component of diffuse large B-cell lymphoma, but overall, there was no difference in

survival for the four histologic subtypes identified: splenic type, floral type, MALT type, and MALT type plus diffuse large B-cell lymphoma.[26] Our practice is to perform Ki67/MIB1 staining in cases of NMZL and to note in the report if the proliferation rate is especially high (>50% of the nucleated cells), but it is not clear whether different therapeutic approaches benefit this subset.[14]

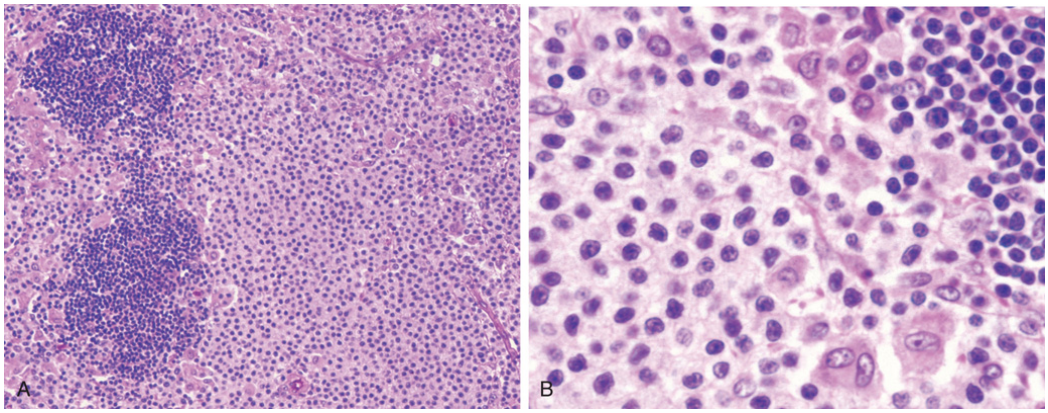

FIGURE 20-2 Secondary extranodal marginal zone lymphoma in the lymph node of a patient with Sjögren syndrome.**A,** Atypical monocytoid cells surround residual follicular structures. **B,** The cells have abundant clear cytoplasm and distinct cytoplasmic membranes.

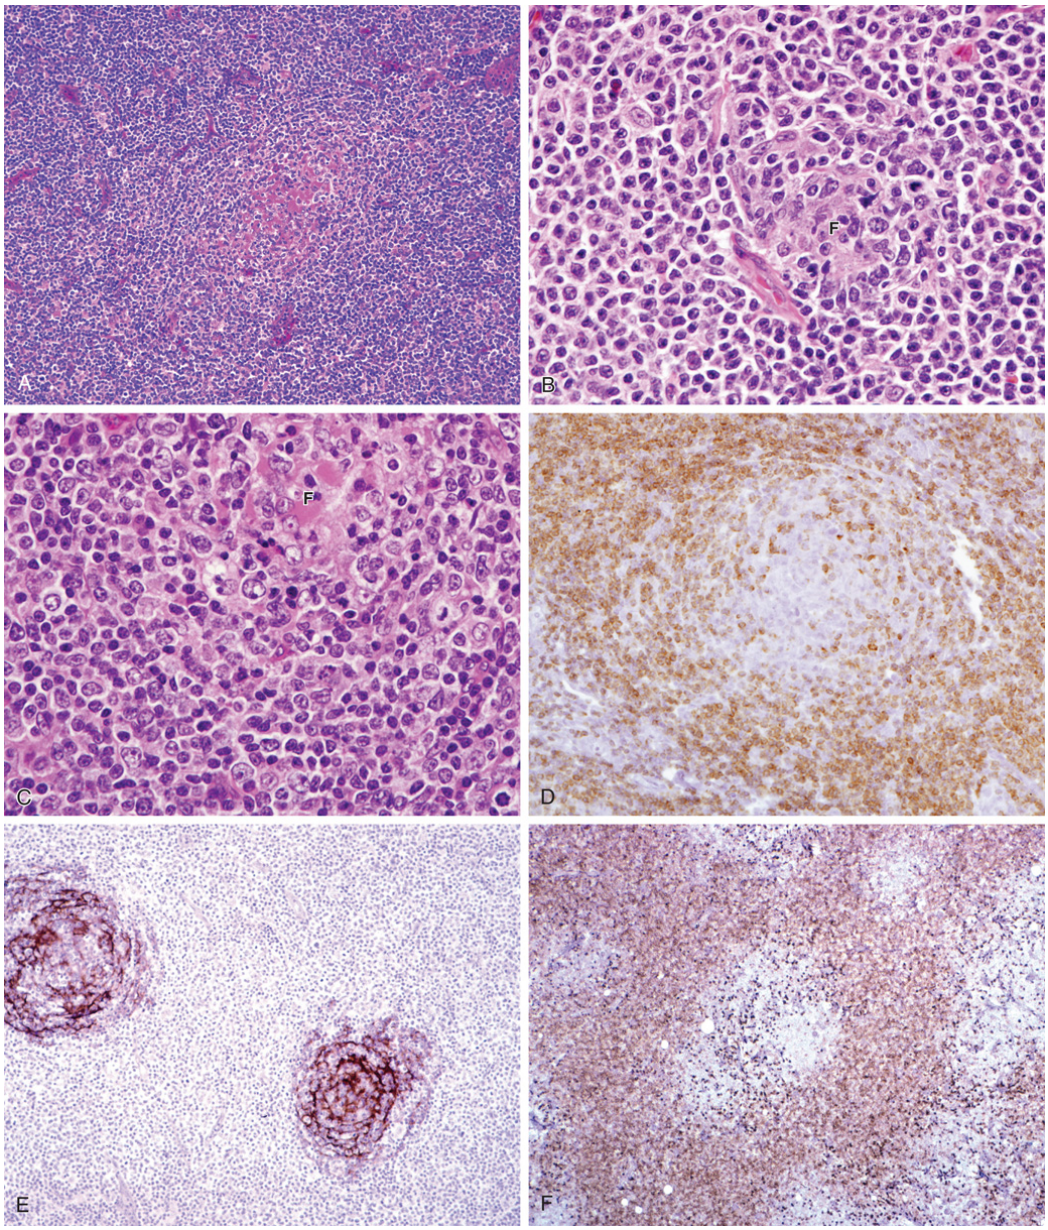

FIGURE 20-3 Nodal marginal zone lymphoma.**A,** Atypical lymphoid cells surround and replace regressed germinal centers. **B,** A small, regressed follicle is present in the center (F). The surrounding cells are slightly irregular, with a rim of pale cytoplasm. **C,** In this example, a higher proportion of blastic cells is present. A regressed follicle is shown (F). **D,** With BCL2

immunostain, the neoplastic marginal zone cells are weakly BCL2 positive, whereas the regressed follicle is negative. **E,** CD21 immunostain highlights follicular dendritic cells in the regressed follicle center. **F,** With IgD immunostain, the neoplastic cells are weakly IgD positive, and the disrupted mantle cells are strongly IgD positive.

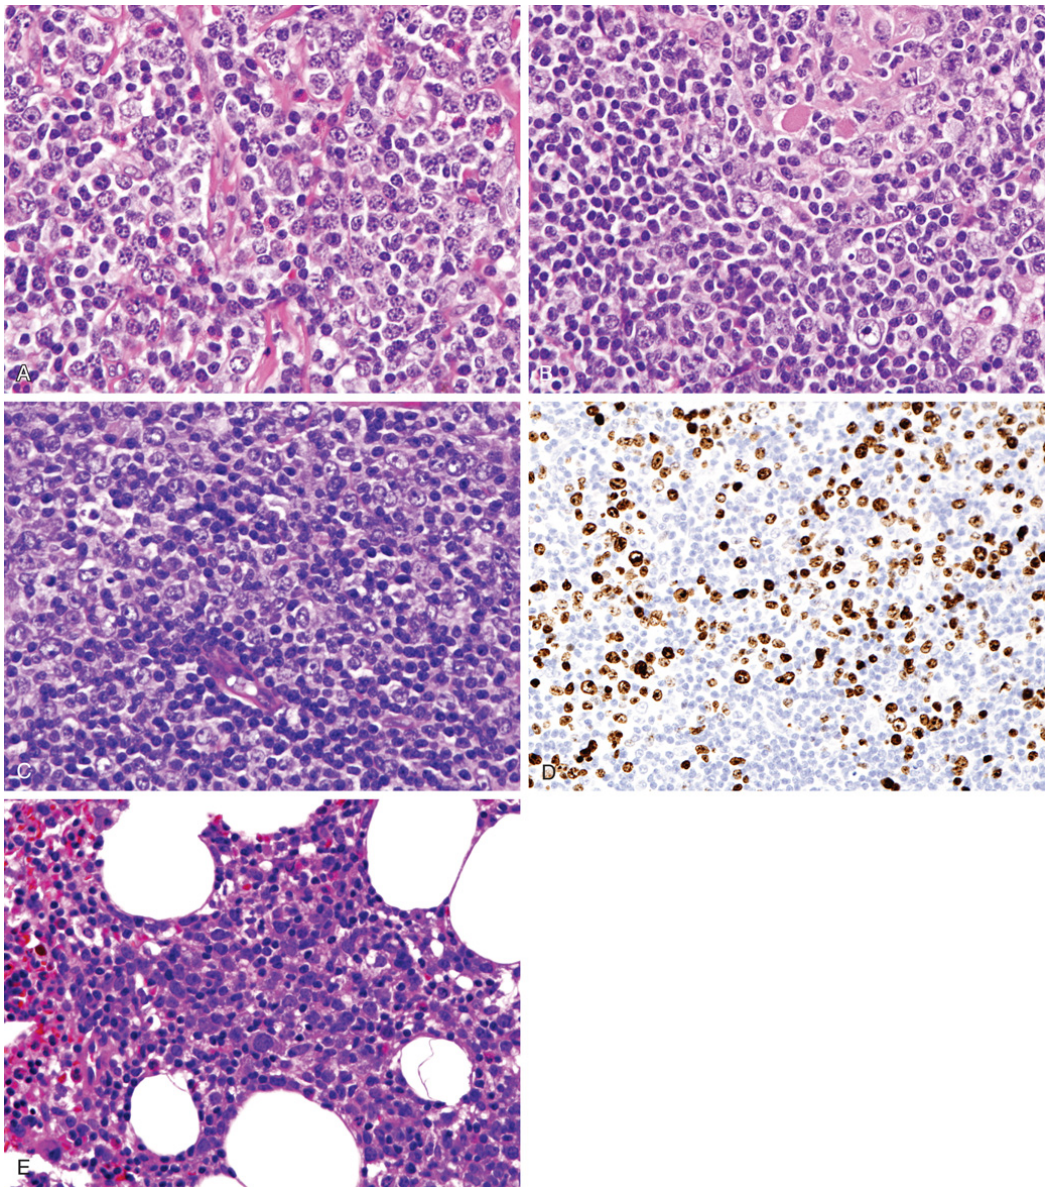

FIGURE 20-4 Varied cytologic composition of nodal marginal zone lymphoma (NMZL).**A,** In this case, plasmacytoid cells are numerous, and eosinophils are increased. **B,** In the same case, a regressed follicle is surrounded by small and large lymphoid cells, including some with blastic features. **C,** In another case, more numerous blastic cells are seen, but a range of cell sizes is

still present. **D,** In the same case as in **C,** the proliferative rate is relatively high, but a range of cell sizes is present (MIB1). **E,** Bone marrow involvement in NMZL. A large cluster of lymphoid cells is present in a non-paratrabecular localization.

Immunophenotype

NMZLs are mature B-cell lymphomas that express CD20, CD19, and CD79a but, in most cases, lack CD5, CD23, CD10, and BCL6. CD43 is positive in up to 50% of cases.[17,18] BCL2 protein is generally weakly positive. IgD is a helpful marker in highlighting the presence of a residual mantle cuff, which often illuminates the pattern of infiltration by the neoplastic cells. The neoplastic cells in MALT lymphomas are almost invariably negative for IgD, whereas variable-to-weak expression of IgD can be observed in 25% to 50% of NMZLs overall.[3,5,17]

Plasmacytoid differentiation is seen in approximately 50% of NMZL cases. When present, the plasmacytoid cells may express MUM1/IRF4, but usually only a subset of the cells with plasmacytoid features, either morphologically or immunophenotypically, are MUM1/IRF4 positive.[5,27] Overall, 25% to 50% of cases express this marker by immunohistochemistry, which first appears in late centrocytes and is thought to indicate commitment to the post–germinal center program.[28] CD38, another marker associated with plasmacytoid differentiation, was positive in 41% of cases in one study.[5] MNDA is an antigen found on myelomonocytic cells but,

interestingly, also expressed in a high proportion of NMZL cases; however, it is absent in FL.[29] Some tumors have a minor cellular component resembling monocytoid B cells, and IRTA may be expressed focally in those cases.[30]

Cytoplasmic Ig expression can be detected in cells exhibiting morphologic evidence of plasmacytoid differentiation and often in the blastic cells, which display a rim of basophilic cytoplasm. In most cases, the cells are IgM positive, but IgG and IgA expression, indicative of heavy chain class switching, has been reported in a small minority.[3] There is a strong bias toward the expression of kappa light chain over lambda light chain; in contrast, in EMZL, kappa and lambda are expressed in a ratio similar to that of normal B cells.[3,5] The distribution of plasmacytoid cells varies within lymph nodes. The plasmacytoid component is usually admixed with other cell types, but in some cases, plasmacytoid cells preferentially colonize germinal centers (**Fig. 20-5**).

The neoplastic cells are generally negative for CD21 and CD23 by immunohistochemistry. However, these markers are useful in highlighting the distribution of residual follicular dendritic cell (FDC) meshworks. In contrast to FLs, in which FDCs highlight the expanded follicular structures, the FDCs in NMZL are typically present in tight clusters, indicative of regressed follicles.[17]

The regressed germinal centers may contain a high content of T cells, giving rise to an inverse follicular pattern in which the neoplastic B cells surround nodules of T cells. Overall, NZML has a relatively high content of infiltrating mature T cells, most of which have a T-follicular helper (TFH) phenotype, positive for PD1.[23] Two main patterns of increased TFH infiltration were observed: follicular

and diffuse. In cases with a dominant follicular pattern, the T cells were either central (replacing the germinal-center compartment), or more peripheral with remnants of residual germinal centers. However, the T-cell infiltrate often extended into the interfollicular region (**Fig. 20-6**). The polymorphous cellular composition, in conjunction with a heavy T-cell infiltrate, led to a suspected diagnosis of peripheral T-cell lymphoma in many of these cases. In this setting, evaluation of T-cell and B-cell clonality by polymerase chain reaction (PCR) analysis may be essential for accurate diagnosis. In about one-third of NMZL cases, T cells were not significantly increased.[23]

In exceptional cases with marked follicular colonization, the FDC meshworks may be expanded.[21] The colonizing cells are negative for the germinal-center–associated markers CD10 and BCL6. There are limited data concerning other prognostic markers in NMZL. As previously noted, staining for Ki67/MIB1 usually stains 20% or fewer of the neoplastic cells. However, clinical data correlating a higher proliferative rate with differences in clinical outcome do not exist.[3] Many low-grade B-cell lymphomas have alterations in the apoptosis pathway, leading to prolonged survival of the neoplastic cells. One study identified strong expression of survivin in approximately 40% of cases, with those patients having considerably decreased survival.[5] The same authors identified loss of active caspase E and increased expression of cyclin E as negative prognostic factors. Activation of the nuclear factor κB (NF-κB) pathway has been implicated in most cases of EMZL.[31] However, NMZLs often lack nuclear expression of BCL10, implying a lack of NF-κB activation in such cases.

Genetics and Molecular Findings

NMZLs show clonal rearrangement of the Ig heavy-chain (IGH) genes, as expected for any clonal B-cell neoplasm. During B-cell development, and as part of the maturation of the high-affinity antibody response, most B cells enter the germinal center and undergo somatic hypermutation (SHM) of the Ig variable region genes.[32] The detection of mutations in these genes is taken as evidence of transit through the germinal center, and germinal-center neoplasms show evidence of ongoing mutations. NMZLs are heterogeneous with respect to SHM frequency. Most studies have shown evidence of SHM,[3,5,33-36] but rare cases are unmutated.[3,33] The B-cell receptors of selected B-cell lymphomas were shown to bind the hepatitis C viral envelope protein, implicating the virus in lymphoma pathogenesis, including NMZL.[37]

Consistent cytogenetic aberrations have not been identified in NMZL.[14] Numerical abnormalities are most common, with reports of +3, +7, +12, and +18 being most frequent.[14,38,39] Both duplication of chromosome 3 and gains in several regions, as identified by comparative genomic hybridization, have been reported.[40,41] Notably, the genetic and genomic changes in NMZL differ from those reported in EMZL and LPL, providing additional evidence for a distinction among these disorders.[41,42] Mutations in MYD88L265P are uncommon in NMZL but are found in more than 90% of cases of Waldenström macroglobulinemia and LPL.[15,16] Although the genomic profile differs from that of EMZL and LPL, NMZL does show evidence of constitutive NF-κB activation in most instances.[43] Gene expression profiling studies showed a pattern resembling

normal marginal zone B cells and memory B cells and differing significantly from that of FL.[44]

High throughput sequencing has identified some recurrent mutations in NZMZL. Notch pathway genes, in particular *NOTCH2,* are mutated in 10% to 20% of cases of NMZL, but also *NOTCH1, SPEN,*[45] and NF-κB genes (*TNFAIP3, BIRC3,* and *TRAF3*). *KLF2* a master regulator of both NOTCH and NF-κB signaling is often mutated in this disease. One study identified *KMT2D* as the most commonly mutated gene in NMZL, found in 20% of cases.[46] An unexpected finding was mutations in *BRAF,* found in nearly 10% of cases.[46] Genomic profiling of diffuse large B-cell lymphoma (DLBL) has shown similarities to that of NMZL with the BN2 cluster of DLBCL, as demonstrated by mutations in *NOTCH2* and *BCL6*.[47] This finding suggests a subset of cases of DLBCL in the BN2 cluster may represent transformed marginal zone lymphoma.

Postulated Cell of Origin

NMZLs are heterogeneous and are thought to be related to different subsets of marginal zone or memory B cells.[33] The morphologic, immunophenotypic, and genetic heterogeneity of these lymphomas is likely a reflection of the involvement of different B-cell subsets found within the marginal zone.[10] Marginal zone B cells can be both IgD positive and negative. They can show low levels of SHM, indicative of a pre–germinal-center stage of maturation, or high levels of SHM.[48] In animal models, a variety of cell types populate the marginal zone, including recirculating virgin B cells that can expand by a T-independent mechanism and memory B cells generated in germinal centers. A direct relationship of NMZL to the

parasinusoidal monocytoid B cells seen in *Toxoplasma* lymphadenitis has not been suggested in most studies.

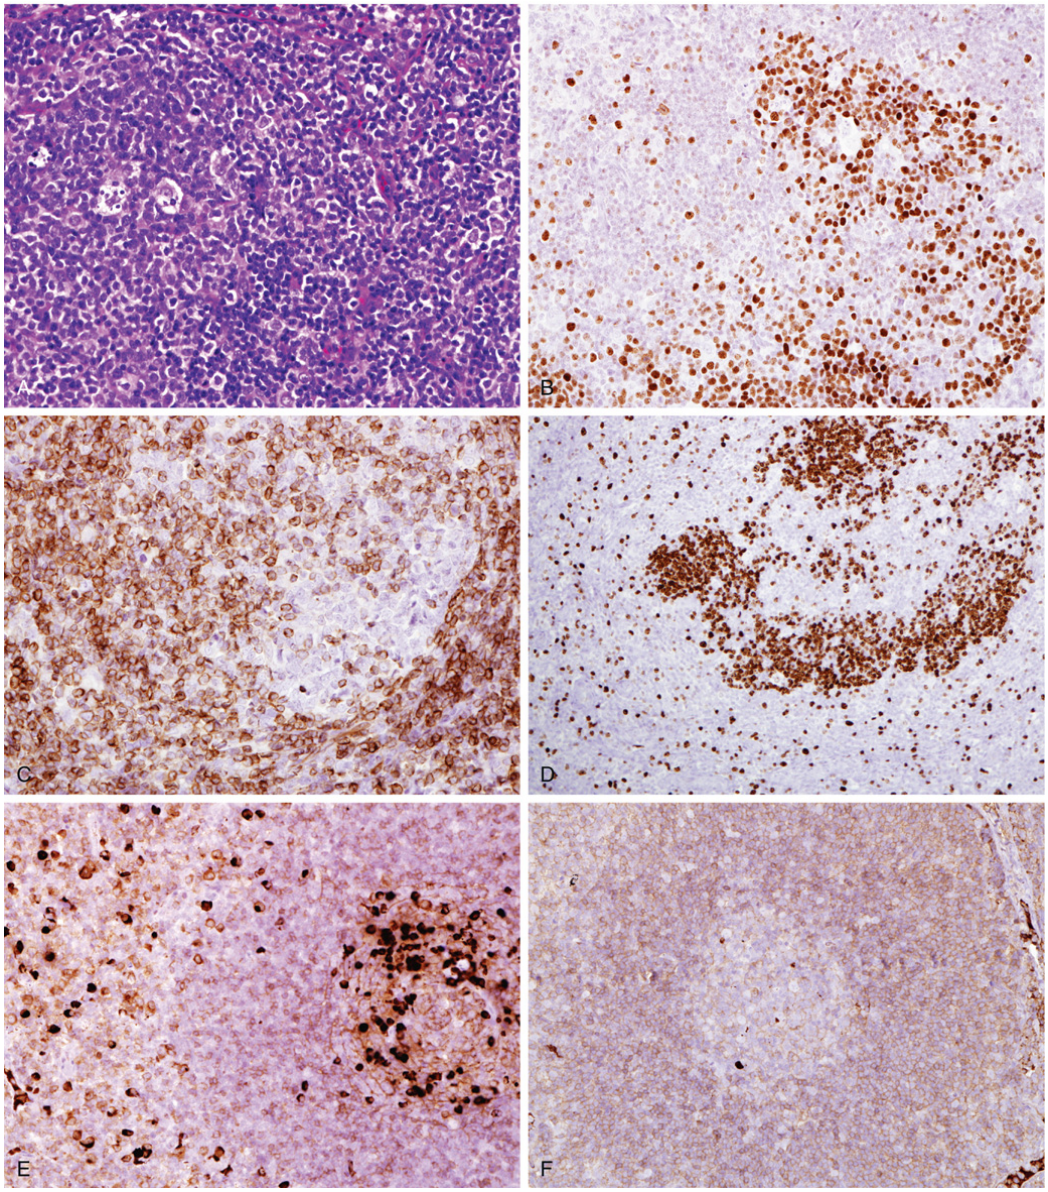

FIGURE 20-5 Follicular colonization in nodal marginal zone lymphoma (NMZL).**A,** Germinal center at left is partially infiltrated and replaced by neoplastic cells. Starry-sky macrophages are noted within the disrupted germinal center. **B,** With BCL6 immunostain, the residual germinal-center cells are BCL6 positive, whereas infiltrating NMZL cells are BCL6 negative. **C,**

With BCL2 immunostain, the infiltrating NMZL cells are BCL2 positive, whereas normal germinal-center cells are BCL2 negative. **D,** Residual germinal center is highlighted by a high proliferation rate with MIB1. The surrounding neoplastic cells have a low proliferation rate. **E,** In another case, the cells colonizing the germinal center show plasmacytoid differentiation and are lambda light chain restricted. Cells outside the germinal center also show light chain restriction. **F,** Kappa is negative in corresponding areas.

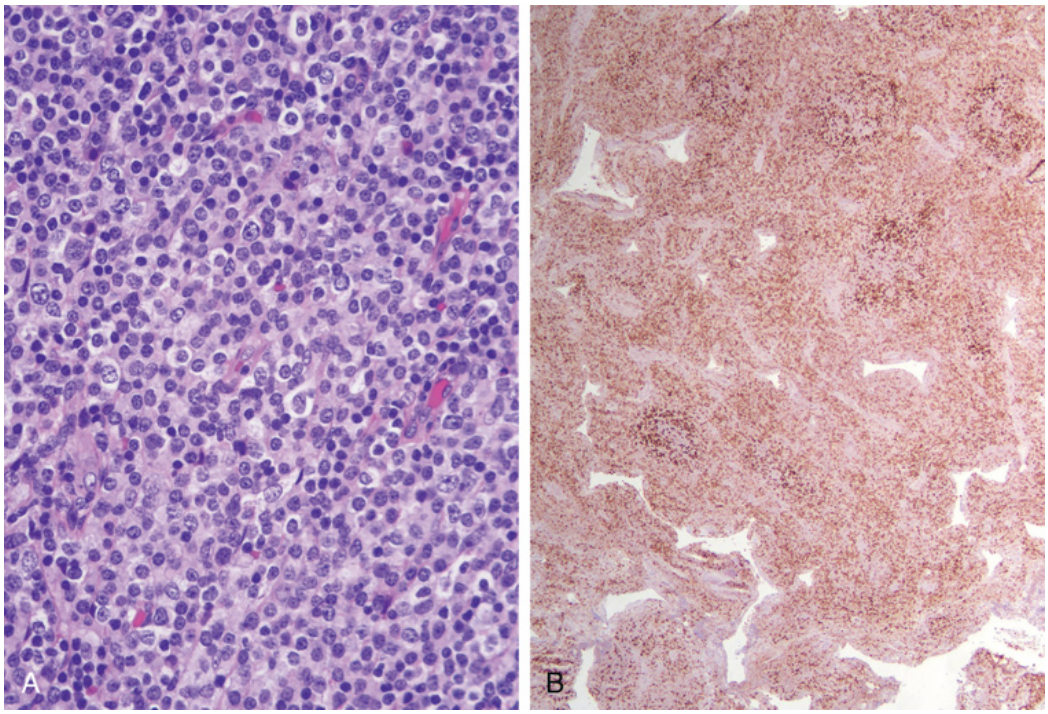

FIGURE 20-6 **A,** Nodal marginal zone lymphoma. Cytologic composition is polymorphic. Most cells have round nuclear contours and ample cytoplasm. Small lymphocytes are appreciated in the background. **B,** Same case is stained for PD1 and shows a marked increase in PD1-positive cells, both in residual regressed follicles and in the interfollicular region. The abundance of PD1-positive lymphocytes may raise concern for peripheral T-cell lymphoma.

Clinical Course and Prognostic Factors

NMZL is considered an indolent or "low-grade" B-cell lymphoma. However, the 5-year overall survival is somewhat less than that seen

for FL and CLL, two of the most common low-grade B-cell neoplasms. Most studies have reported 5-year overall survival in the range of 55% to 75%, with better outcomes in more recent series, possibly reflecting the increased use of rituximab.[3,5,14,26] The complete remission rate is approximately 50%, with progression-free or event-free survival at 5 years generally between 30% and 40%.[14] Because most patients are in the low or low-intermediate IPI risk groups, the IPI has not been especially useful as a prognostic marker; however, the FLIPI appears to be more predictive.[4,6]

PEDIATRIC-TYPE NODAL MARGINAL ZONE LYMPHOMA (PT-NMZL)

Synonym (proposed): Pediatric-type follicular lymphoma with marginal zone differentiation.

Morphology and Immunophenotype

Cases resembling NMZL presenting in the pediatric age group have distinctive morphologic and clinical features, and in the 2016 update of the World Health Organization classification, these lesions were delineated as a provisional entity.[49,50] In affected lymph nodes, the atypical cells have a predominantly interfollicular distribution, with marked expansion of the marginal zone (**Fig. 20-7**). The infiltrate is polymorphic, composed of monocytoid cells, centrocyte-like cells, and plasma cells.[24,51] Blasts are usually present but few in number—no more than two or three per high-power field. A characteristic feature, seen in most pediatric cases (70%), is follicular expansion, sharing some features with progressive transformation of germinal centers. The appearance of these atypical follicles is similar to that of

the floral variant of FL and shows overlap with the atypical follicles seen in the pediatric type of FL (PTFL).[52,53] In contrast to typical progressive transformation of germinal centers, the peripheral rims of the follicles are irregular, with blurring and disruption by the atypical proliferation in the marginal zone. The overall size of the follicles is expanded; the fragmented and irregular mantle zones are best visualized with stains for IgD. Early reports noted difficulties in the differential diagnosis with PTFL (see **Chapter 17**). In fact, more recent studies have shown more marked overlap, with 69% of cases showing remarkably similar features and a continuum in the involvement of the follicular versus marginal zone component.[54,55] Moreover, in subsequent genomic studies, it was shown that "pediatric NZML" and PTFL share a common profile and are likely part of the same biological and clinical entity.[54] As will be discussed, they also share a similar clinical profile. In some cases, plasmacytoid differentiation is best documented by stains for cytoplasmic Ig, and small numbers of atypical cells may show light chain restriction in both the interfollicular and follicular components. However, marked plasmacytoid differentiation is rare. The current view is that PT-NMZL and PTFL are a single disease entity with variation in the histologic pattern and expansion of B-cells in both the marginal zone and follicular compartment. Early reports of PTFL noted evidence of marginal zone differentiation surrounding the atypical follicles.[52,53]

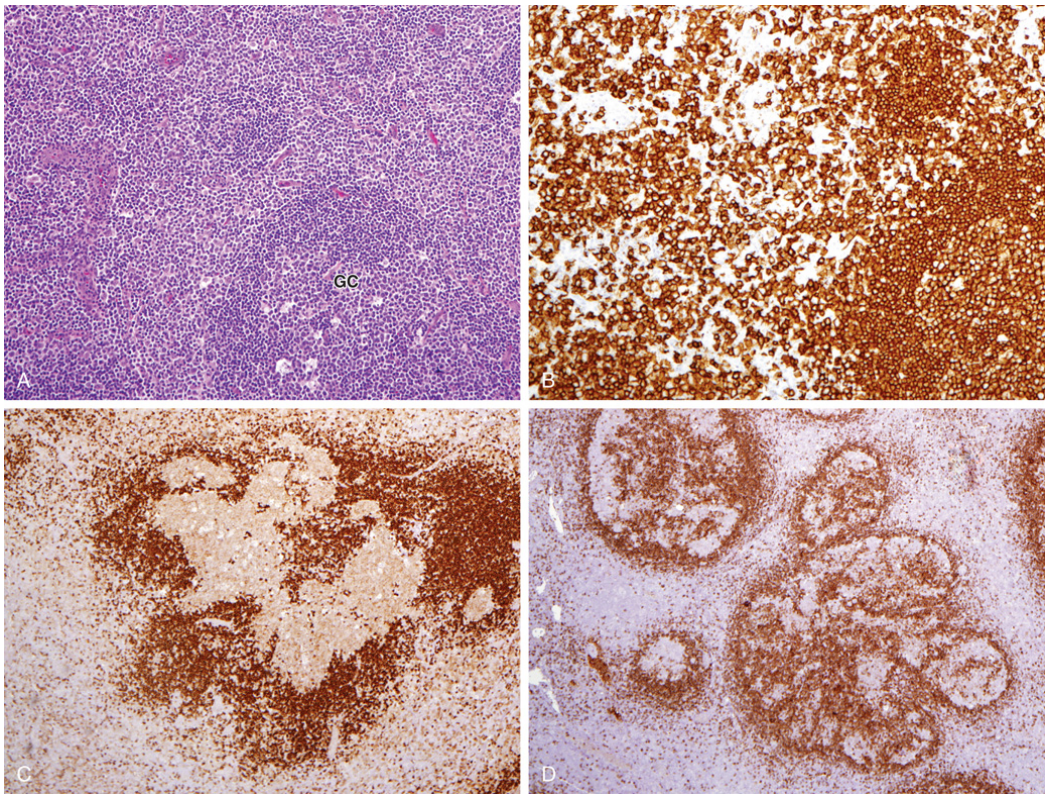

FIGURE 20-7 Pediatric-type nodal marginal zone lymphoma in the cervical lymph node of an 11-year-old girl.**A,** Atypical cells expand in the marginal zone and focally infiltrate a follicle (GC). **B,** CD20 staining of the same case shows numerous B cells in the marginal zone. **C,** Immunoglobulin (Ig)D highlights the expanded mantle zone around some of the follicles. The germinal center is partially disrupted and fragmented by the IgD mantle cells, a feature resembling progressive transformation of germinal centers. **D,** The patient received no treatment after surgical excision of the lymph node. Recurrence developed 4 years later, showing similar follicular disruption resembling

progressive transformation of germinal centers (IgD immunostain).

The differential diagnosis of PT-NMZL, especially in children, includes atypical marginal zone hyperplasia, which can present in MALT in Waldeyer's ring or the small intestine. In the report by Attygalle and coworkers,[56] these cases all showed lambda light chain restriction but failed to show evidence of clonality at the genetic level by PCR analysis for IGH gene rearrangement. This novel form of marginal zone hyperplasia has been linked to a response to *Haemophilus influenzae*.[57]

Genetic Features

Clonality is best confirmed by PCR studies for clonal rearrangement of the IG genes, which yield a positive result in more than 80% of cases tested.[58] Molecular analysis revealed that PT-NMZL shows a low level of genetic complexity similar to PTFL.[54] The mutational profile of PT-NMZL was also found to be distinct from adult-type NMZL. Mutations in *MAP2K1, TNFRSF14,* and *IRF8* were most commonly found, similar to PTFL. This mutational profile was seen in 78% of cases with morphologic overlap with PTFL, but also in cases lacking significant overlap (61%). One difference with PTFL was that 1p36 CNN loss of heterozygosity (LOH) or deletion was uncommon in cases classified as PT-NMZL.

Clinical Features

The median age at presentation for PT-NMZL is 16 years. There is a striking male predominance, with a 20:1 male-to-female ratio for patients younger than 20 years of age, similar to PTFL. The most

common presentation of PT-NMZL is asymptomatic lymphadenopathy involving the head and neck region, most commonly the cervical nodes. The majority of patients have localized stage I disease and show a low rate of recurrence after conservative treatment. This clinical behavior contrasts with that of NMZL in adults. For these reasons, conservative management consisting of clinical observation after surgical excision is recommended for patients with disease in a single lymph node. This is comparable to the management of PTFL.

Differential Diagnosis

Extranodal Marginal Zone Lymphoma

Patients with EMZL can have lymph node involvement, sometimes many years after the initial diagnosis (see **Chapter 18**). Therefore, a careful clinical history is most important in distinguishing lymph node involvement by EMZL from that of NMZL. Histologic features more common in EMZL include well-preserved reactive follicles with intact mantle cuffs and a prominent component of monocytoid B cells.[17] EMZLs are nearly always negative for IgD, whereas primary NMZL may be positive (**Table 20-1**).

Lymphoplasmacytic Lymphoma

One of the more challenging and difficult differential diagnoses is between LPL and NMZL (see **Chapter 14**). In LPL, the lymph node sinuses are often preserved, whereas in NMZL, the architecture is generally more effaced (**Fig. 20-8**). The infiltrate in LPL is more uniform, with a relatively monotonous infiltrate of small lymphoid cells with plasmacytoid features. The plasmacytoid cells are usually

most prominent adjacent to the lymph node sinuses, and diffuse architectural effacement may be seen in some cases. Dutcher bodies are present in most cases, and increased mast cells can be documented with Giemsa stain. Lymphoid follicles, if present, are usually regressed. It should also be noted that the genetic aberrations in LPL associated with Waldenström macroglobulinemia differ from those seen in NMZL.[15,16,59] The characteristic *MYD88* L265P mutation can be readily detected by PCR analysis of DNA extracted from formalin-fixed paraffin-embedded sections and is useful in borderline cases. Notably, the MYD88L265P mutation has been reported only rarely in NMZL, but of course, it is known to occur in diffuse large B-cell lymphoma of the ABC subtype.[60] Therefore, presence of the mutation does not automatically exclude a diagnosis of NMZL.

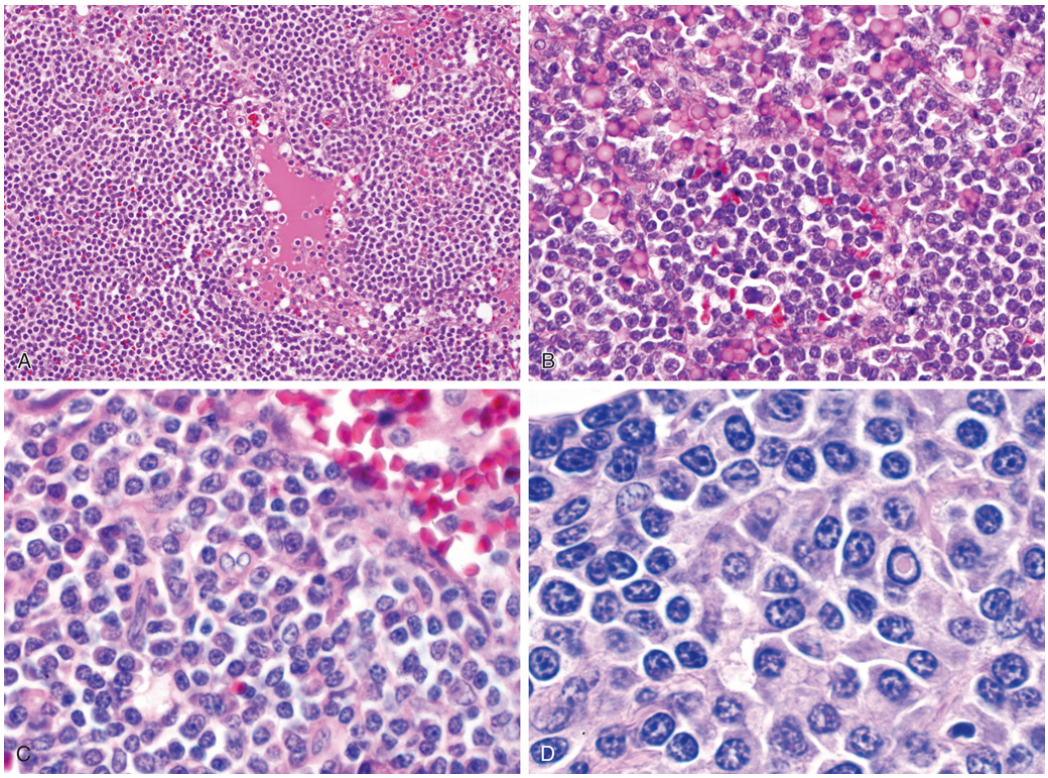

FIGURE 20-8 Lymphoplasmacytic lymphoma (LPL).**A,** The infiltrate in LPL is more monotonous than that in nodal marginal zone lymphoma (NMZL). Sinuses are intact and often dilated. **B,** Numerous Mott cells with cytoplasmic globular inclusions are present. Surrounding cells show plasmacytoid features. **C,** Plasmacytoid lymphocytes are usually most conspicuous adjacent to sinuses. **D,** Dutcher bodies are more common in LPL than in NMZL but can be seen in either disease.

Table 20-1

CLL/SLL, Chronic lymphocytic leukemia/small lymphocytic lymphoma; *EMZL,* extranodal marginal zone lymphoma; *Ig,* immunoglobulin; *LPL,* lymphoplasmacytic lymphoma; *NMZL,* nodal marginal zone lymphoma.

* Pseudofollicular growth centers.

† Reported in rare cases.

Marginal Zone Hyperplasia and Related Reactive Conditions

The normal marginal zone is much less conspicuous in the lymph nodes than it is in the spleen. In peripheral lymph nodes, it is difficult to identify this region under normal circumstances.[61] Mesenteric lymph nodes usually have a more well-developed marginal zone. This region can be distinguished from primary follicles or mantle cuffs because the cells are negative for IgD by immunohistochemistry. Normal marginal zone B cells can express BCL2; therefore, BCL2 reactivity is not helpful in distinguishing benign from malignant marginal zone expansions.[62] The marginal zone can be expanded in some reactive conditions, placing NMZL in the differential diagnosis.[63] Identification of light chain restriction by immunohistochemistry or flow cytometry favors NMZL. However, some cases of marginal zone hyperplasia, particularly in children, can show restricted expression of lambda light chain.[56] Molecular studies for clonal rearrangement of the IG genes are recommended because clonal rearrangements should be absent in marginal zone hyperplasia.

Another process that may mimic the follicular colonization seen in some NMZLs is atypical hyperplasia with monotypic plasma cells found in the germinal centers.[64] These cases usually lack evidence of a monoclonal process at the molecular level, although in a minority, evidence of monoclonality can be found in the microdissected lesions. This form of hyperplasia is more common in women and may be associated with a background of autoimmune disease. Thus, it may be related pathogenetically to the development of some marginal zone neoplasms.

Monocytoid B-Cell Hyperplasia

Marginal zone hyperplasia should be distinguished from monocytoid B-cell hyperplasia, although historically, these cell types have been confused. A prominent monocytoid B-cell reaction is classically seen in acute acquired toxoplasmosis but can also occur in a variety of other reactive conditions, including reaction to cytomegalovirus infection and the lymphadenopathy associated with human immunodeficiency virus infection.[65,66] Normal monocytoid B cells are found in a parasinusoidal distribution adjacent to the subcapsular and medullary sinuses in lymph nodes and may be significantly expanded in this region. They are usually associated with admixed polymorphonuclear lymphocytes. In contrast to normal marginal zone B cells, monocytoid B cells are negative for BCL2.

Follicular Lymphoma

Some cases of FL may show marginal zone differentiation, mimicking NMZL.[67] In such cases, the atypical follicles usually have

an attenuated or ill-defined lymphoid cuff surrounded by a polymorphic infiltrate of cells with more abundant cytoplasm than the follicle center cells (**Fig. 20-9**). Blastic cells and cells with monocytoid features are usually present. The marginal zone component may differ immunophenotypically from the follicle center cells and often shows downregulation of CD10. BCL6 may be weakly expressed. The follicle center cells are positive for BCL6 and, in most cases, positive for BCL2 and CD10. However, some higher-grade FLs are negative for CD10 and show increased expression of MUM1/IRF4.[68] The diagnosis is more challenging in such cases because MUM1/IRF4 is expressed in post–germinal-center B cells and may be expressed in NMZL. Further complicating the matter is the frequent absence of *BCL2::IGH* translocations in these FL variants.[69] Amplifications of *BCL6* may be present, favoring a follicle center derivation.

The principal differential diagnosis is NMZL with follicular colonization, in which the colonizing cells should be negative for the germinal-center–associated markers BCL6 and CD10 but may express BCL2 protein in the absence of the *BCL2::IGH* translocation. Evidence of plasmacytoid differentiation, in either the intrafollicular or extrafollicular compartment, favors NMZL but can be seen rarely in FL.[70]

It is important to note that NMZL is negative for CD23, but CD23 is highly expressed in certain variants of FL that are negative for *BCL2* rearrangement.[71] This FL variant often presents with localized inguinal involvement and may have a largely diffuse growth pattern, raising the differential diagnosis of NMZL.

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma With a Parafollicular Pattern

Some cases of chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) have a parafollicular pattern of involvement in lymph nodes that superficially resembles NMZL (**Fig. 20-10**).[72] The infiltrate is usually monotonous, typical of CLL/SLL, and contains pseudofollicular growth centers. Attenuated lymphoid cuffs may be seen and are more readily identified with stains for IgD. With immunohistochemical studies, the typical CLL/SLL phenotype is present: CD5-positive, CD23-positive, LEF1-positive B cells with dim CD20 expression.

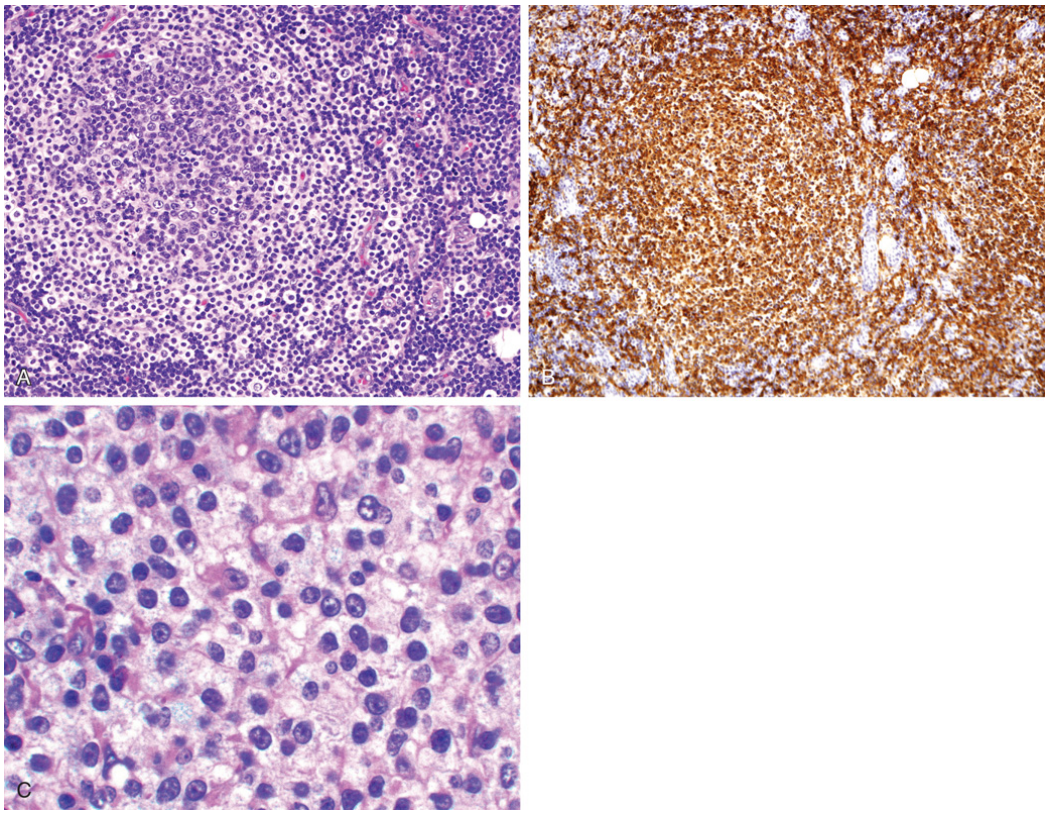

FIGURE 20-9 Follicular lymphoma with marginal zone differentiation.**A,** Periphery of the neoplastic follicle is composed of cells with monocytoid features. **B,** CD10 staining of the same case. Both monocytoid cells and more typical follicular-lymphoma cells are CD10 positive. **C,** Monocytoid cells have abundant clear cytoplasm and distinct cytoplasmic membranes.

Splenic Marginal Zone Lymphoma

SMZL usually presents with marked splenomegaly and bone marrow involvement without significant peripheral lymphadenopathy. Splenic hilar lymph nodes usually show intact sinuses with a small lymphocytic infiltrate that replaces preexistent structures, including

follicles.[73,74] Interestingly, the cells in splenic hilar lymph nodes usually do not show monocytoid or marginal differentiation and have relatively sparse cytoplasm. However, lymph node involvement can also occur during the course of SMZL and may resemble NMZL (**Fig. 20-11**).

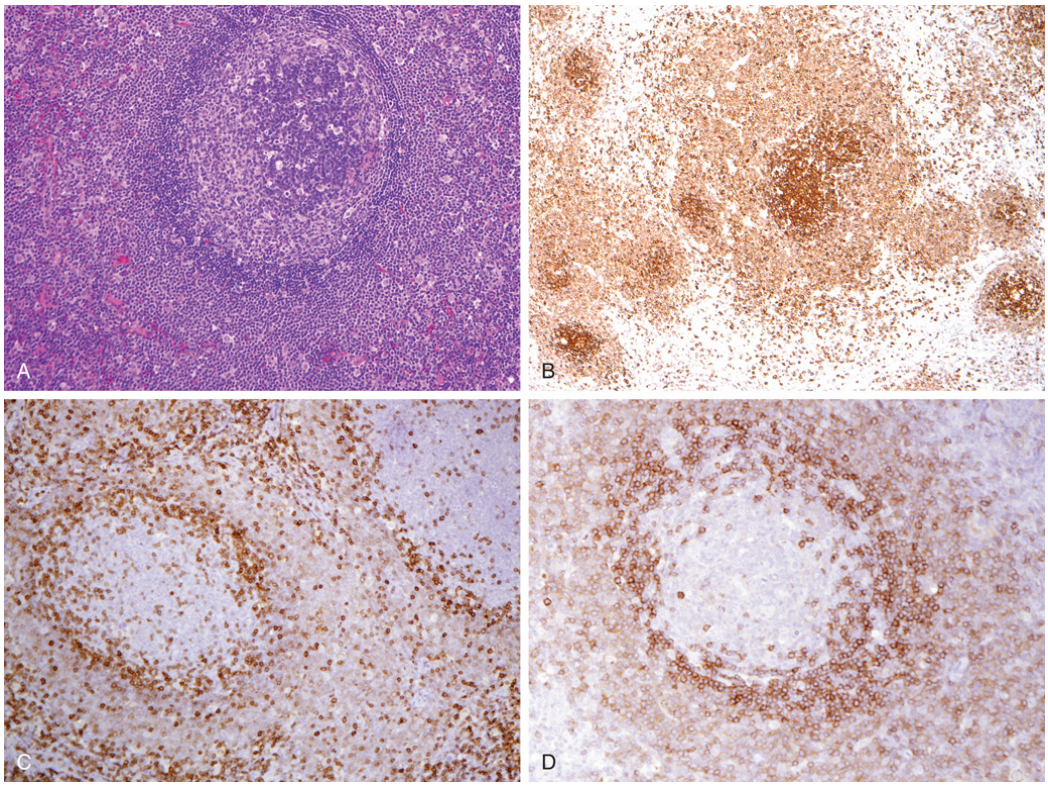

FIGURE 20-10 Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) with a parafollicular marginal zone pattern.**A,** Reactive follicle is surrounded by a rim of CLL cells, resembling an expanded marginal zone. **B,** CLL cells show dim CD20 expression, contrasting with more intense staining of follicular B cells. **C,** CLL cells show dim CD5 expression. There is a thin rim of CD5-positive T cells at the periphery of the germinal center. **D,** The thin mantle cuff is strongly IgD positive, whereas the CLL cells are dimly IgD positive.

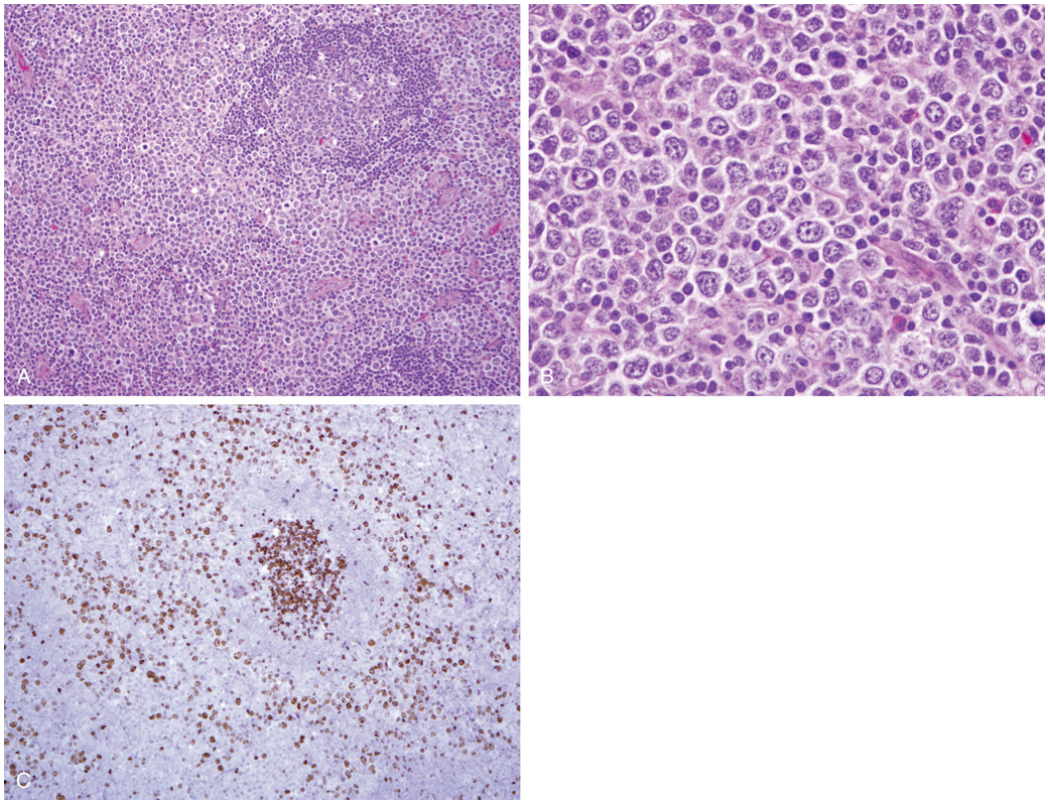

FIGURE 20-11 Splenic marginal zone lymphoma recurrence in a lymph node.**A,** Medium-to-large lymphoid cells surround the residual reactive follicle. **B,** At high power, cells show a spectrum of sizes. **C,** Overall, the proliferation rate of the lymphoma is low, although cells abutting the reactive follicle show a somewhat higher proliferation rate (MIB1/Ki67).

Pearls and Pitfalls

- NMZL is most often a diagnosis of exclusion, after other low-grade B-cell lymphoma subtypes have been ruled out.

- In NMZL with prominent monocytoid B cells (MALT type), the diagnosis of secondary EMZL should be considered and ruled out clinically.
- Both NMZL and LPL may show plasmacytoid differentiation.
  - NMZL contains many different cell types—polymorphic cytology.
  - LPL contains few cell types—monomorphic cytology.
- NMZL with follicular colonization may closely mimic FL.
- The proportion of "blastic" or transformed cells varies widely, but no grading of NMZL is required or recommended.
- The pediatric type of NMZL usually presents with localized, stage I disease and is currently considered part of the spectrum of PTFL.

DEFINITION

Mantle cell lymphoma (MCL) is a mature B-cell neoplasm generally composed of monomorphic small-to-medium-sized lymphoid cells with irregular nuclei that frequently express CD5 and carry *CCND1* rearrangements with immunoglobulin (IG) genes, leading to overexpression of cyclin D1. Some tumors with similar morphology and phenotype have instead *CCND2* or *CCND3* translocations and are also considered as conventional MCL (cMCL).[1] Neoplastic transformed cells (centroblasts), paraimmunoblasts, and pseudofollicles are absent.[2]

Historically MCL was initially recognized as *centrocytic lymphoma* in the Kiel classification,[3] and different subtypes of B-cell lymphomas in the American literature under the terms *lymphocytic lymphoma of intermediate differentiation,*[4] *intermediate*

lymphocytic lymphoma,[5] and *mantle zone lymphoma*.[6] The characterization of the t(11;14) translocation targeting *CCND1* as the genetic hallmark of all these tumors and the identification of mantle cells as the normal counterpart led to a better definition and recognition of the broad clinical and pathologic spectrum of the disease.[7,8] The biological behavior of most MCLs is very aggressive although the outcome of the patients is improving with novel therapeutic strategies. In contrast with this cMCL, a different biological and clinical subtype of the disease with an indolent behavior has been recognized and named *leukemic non-nodal MCL* (nnMCL). These patients usually present with leukemic phase, frequent splenomegaly, but no or minimal nodal involvement in the initial phases of the disease.[9,10]

Proposed WHO 5th ed.: Mantle cell lymphoma

EPIDEMIOLOGY

MCL represents 2.5% to 10% of all lymphoid neoplasms and occurs predominantly in older adult men (male-to-female ratio, 2.1 to 3.9:1) with a median age of approximately 65 years (range, 23 to 96 years) (**Table 21-1**). The mean annual incidence of this lymphoma estimated from population-based studies is 0.71 per 100,000 (range, 0.42 to 1.01), with a mean of 0.97 for men and 0.44 for women.[11-16] Recent estimation of familial relative cancer risk (FRR) has shown that MCL displayed one of the highest FRR for the same tumor type among hematological malignancies.[17] Previously, epidemiologic

studies had reported twofold significant increase of hematological neoplasms among first-degree relatives of patients with MCL.[18-20] In occasional patients, germline mutations in *ATM* and *CHK2* have been reported, but like chronic lymphocytic leukemia (CLL), these genes are not involved in the few studied families with lymphoid neoplasms and MCL.[21] Germline variants in DNA repair genes have been described in early onset MCL.[22]

CLINICAL MANIFESTATIONS

More than 70% of patients present with stage IV disease, generalized lymphadenopathy, and bone marrow involvement; bulky disease and B symptoms are less common (see **Table 21-1**).[2,11,12,14-16,23,24] Hepatosplenomegaly is relatively frequent, and massive splenomegaly is observed in 30% to 60% of cases, particularly in the nnMCL subtype.[15,25,26] Some patients have prominent splenomegaly with minimal or absent peripheral lymphadenopathy. This presentation is usually associated with peripheral blood involvement, and the differential diagnosis with other lymphoid leukemias may be difficult.[27,28]

Extranodal involvement is frequent in MCL with more than two sites occurring in 30% to 50% of patients. However, an extranodal presentation without apparent nodal involvement occurs in 4% to 15% of cases.[29] Gastrointestinal (GI) infiltration has been reported in 10% to 25% of patients, either at presentation or during the course of the disease. A peculiar manifestation of this involvement is lymphomatoid polyposis, in which multiple lymphoid polyps are identified in the small and large bowel. These patients may present with abdominal pain and melena.[30,31] Isolated involvement of the GI

tract has been associated with a more favorable outcome than cases presenting with lymphadenopathy.[29] Central nervous system involvement occurs in 1% of patients at diagnosis, but it may appear late in the clinical course in 4% of the patients and has an ominous significance.[32,33] These patients frequently have blastoid morphology, high lactate dehydrogenase (LDH), high MCL International Prognostic Index (MIPI), extensive infiltration in other extranodal localizations, and a leukemic phase.[32,33] Other extranodal sites commonly involved are Waldeyer's ring, lung, and pleura (5%–20%). Less common localizations are skin, breast, soft tissue, thyroid, salivary gland, peripheral nerve, conjunctiva, and orbit.[15,25,26,34-38]

Table 21-1

Peripheral blood involvement at diagnosis varies among studies, depending in part on the disease definition. Conventional examination may detect leukemic involvement at diagnosis in 20% to 70% of patients. Atypical lymphoid cells may be observed in the peripheral blood in the absence of lymphocytosis,[39] and they may be detected by flow cytometry in virtually all patients.[40] Leukemic involvement may also appear during the evolution of the disease and may represent a manifestation of disease progression.[41,42] Some patients present with a very aggressive leukemic form mimicking acute leukemia. These cases have blastoid morphology; complex karyotypes, occasionally with 8q24 anomalies and *MYC* rearrangements, and a very rapid evolution, with a median survival of 3 months.[43-47]

nnMCL usually presents with a leukemic phase and no or minimal lymph node involvement.[27,28,48-50] The patients may have a long period of an asymptomatic atypical lymphocytosis, followed by the development of splenomegaly without nodal dissemination. The disease may be controlled with splenectomy without chemotherapy for long periods. Some of these patients may eventually progress with an aggressive disease with or without nodal dissemination.

Anemia and thrombocytopenia occur in 10% to 40% of patients, and high LDH and β_2-microglobulin levels are detected in approximately 50% of cases. A monoclonal serum component, usually at low levels, has been reported in 10% to 30% of patients.[35,51,52] However, the immunoglobulin isotype is different in the serum and tumor cell surface in some cases. A significant increase of second neoplasm associated with MCL has been reported in around 10% of patients, with a predominance of skin, thyroid, CLL, and other lymphoid neoplasms and solid tumors.[53]

MORPHOLOGY

The pathologic characteristics of MCL are relatively distinctive, but the similarities between some morphologic variants and other lymphoid neoplasms require the use of ancillary studies to clarify the differential diagnosis (**Table 21-2**).

Architectural Patterns

Nodal involvement by MCL usually effaces the architecture with three growth patterns: mantle zone, nodular, or diffuse (**Fig. 21-1**). The mantle zone pattern is characterized by expansion of the follicle mantle area by tumor cells surrounding a reactive “naked” germinal

center. This pattern may be associated with partial preservation of the nodal architecture and may be difficult to distinguish from follicular or mantle cell hyperplasias.[54] Transitional areas between nodular and diffuse patterns are common, but in rare cases, nodularity is prominent, leading to a misinterpretation of follicular lymphoma.[41] However, some nodules may be solid, without evidence of residual germinal centers, representing the malignant counterpart of primary follicles. Alternatively, the nodular pattern may be caused by a massive infiltration and obliteration of the original germinal center by tumor cells. In some cases, cyclin D1 staining may help identify initial infiltration or colonization of reactive germinal centers, which may correspond to early stages of a nodular pattern (**Fig. 21-2**). Residual germinal centers can also be seen in tumors with a more diffuse pattern, although in these cases, they may be identified only focally.

Table 21-2

Cytologic Variants

Classic (common or typical) MCLs are characterized by a monotonous proliferation of small-to-medium-sized lymphoid cells with scant cytoplasm, variably irregular nuclei, evenly distributed condensed chromatin, and inconspicuous nucleoli (**Fig. 21-3**). Large cells with abundant cytoplasm or prominent nucleoli are rare or absent; when present, they may correspond to reactive centroblasts of residual germinal centers overrun by lymphoma cells. Occasional cases may show a predominance of small lymphocytes with round nuclei (**Fig. 21-3**). This small cell variant may be difficult to

distinguish from CLL/small lymphocytic lymphoma (CLL/SLL). However, proliferation centers or isolated prolymphocytes and paraimmunoblasts are absent in MCL. Proliferative activity in classic and small-cell MCL varies from case to case but is usually lower than one to two mitoses per high-power field. However, some tumors with a classic morphology may show a high mitotic index, similar to the blastoid variants, and these patients may have an aggressive clinical course.[55,56] Scattered epithelioid histiocytes with eosinophilic cytoplasm are relatively common, but well-formed microgranulomas are not usually seen (**Fig. 21-4**). These histiocytes generally do not contain phagocytosed apoptotic bodies. Nuclei of follicular dendritic cells with the typical features of overlapping nuclei, delicate nuclear membranes, and an “empty” chromatin appearance are frequently identified. In some cases, hyalinized small vessels may be seen scattered throughout the tumor.

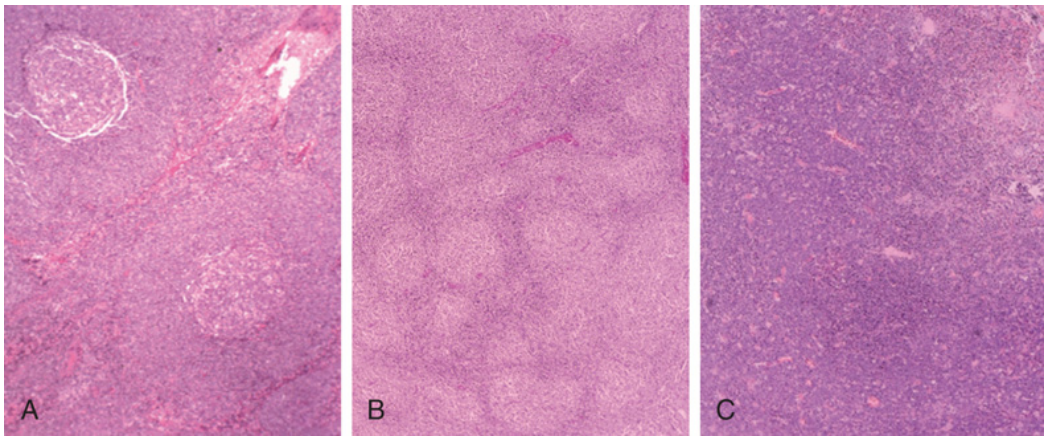

FIGURE 21-1 Architectural patterns in mantle cell lymphoma.**A,** Mantle zone pattern: the tumor cells expand the mantle cell cuff surrounding a reactive germinal center. **B,** Nodular pattern. **C,** Diffuse pattern.

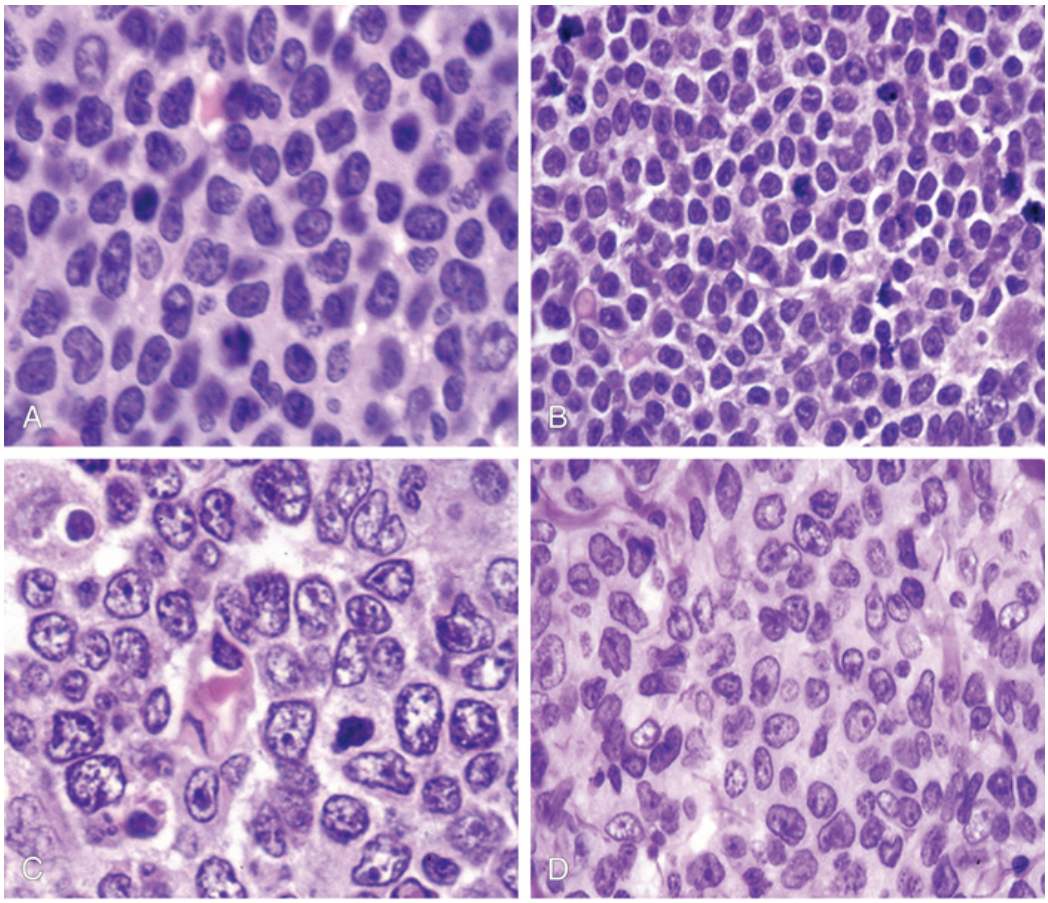

FIGURE 21-3 Cytologic variants of mantle cell lymphoma.**A,** Typical or classic mantle cell lymphoma (MCL) is characterized by small-to-medium-sized lymphocytes with irregular nuclei, condensed chromatin, and scant cytoplasm. **B,** The small-cell variant is composed of small lymphocytes with round nuclei. **C,** The blastoid variant has round nuclei, finely distributed chromatin, inconspicuous or very small nucleoli, and a high mitotic index. **D,** The pleomorphic variant with large cells and very irregular nuclei.

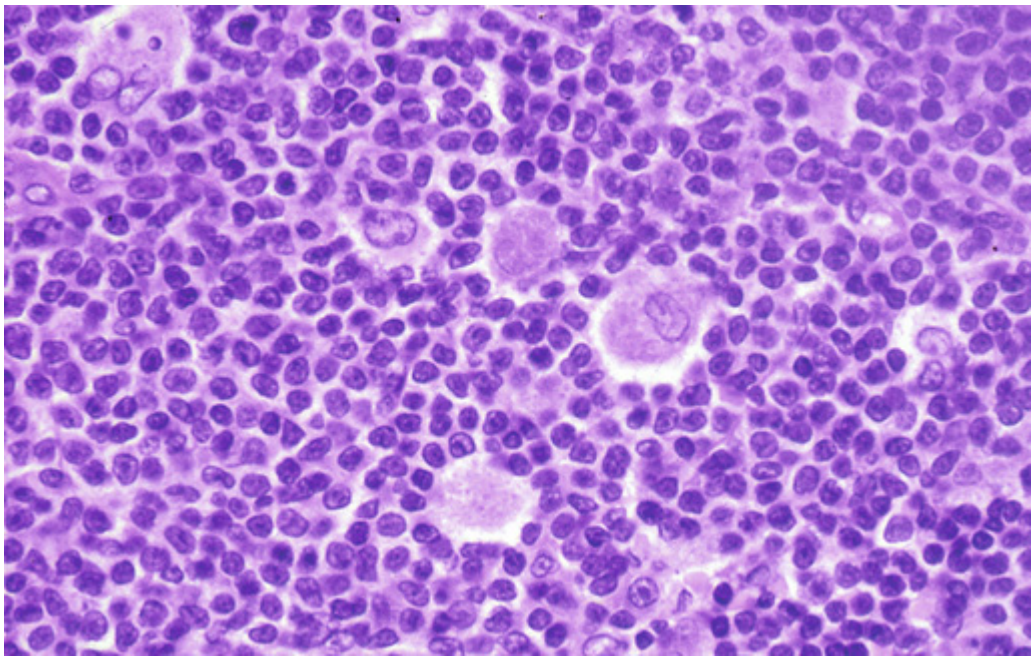

FIGURE 21-4 Classic variant of mantle cell lymphoma with scattered histiocytes with eosinophilic cytoplasm.

More aggressive variants of MCL may have a morphology that ranges from a monotonous population of cells resembling lymphoblasts (blastoid variant) to a more pleomorphic appearance with larger irregular cells resembling diffuse large B-cell lymphoma (**Fig. 21-3**).[36,57-60] Blastoid MCL are characterized by a monotonous proliferation of intermediate-sized cells with round nuclei and fine dispersed chromatin. Pleomorphic MCL are composed of a heterogeneous population of large cells with ovoid or irregular, cleaved nuclei; finely dispersed chromatin; and small, distinct nucleoli (**Fig. 21-3**). The mitotic index is high but usually lower than in blastic cases.[59,61] In some cases, mitotic figures may show a striking hyperchromatic staining, with an apparently high number of chromosomes, usually associated with the presence of

tetraploid clones.[62] This pleomorphic variant may be difficult to distinguish from large-cell lymphomas. However, the nuclear characteristics of cleaved contours, finely dispersed chromatin, and discordance between the large nuclei and relatively small nucleoli may suggest a mantle cell origin. Some leukemic MCLs, described as *prolymphocytic variants* of MCL, may in fact represent leukemic forms of the pleomorphic subtype of MCL.[63-66]

Some cases may have a variable number of cells with more abundant pale cytoplasm, mimicking monocytoid B cells (**Fig. 21-5**).[67] The nucleus of these cells may have blastoid or classic morphology, but the peculiar cytoplasm may raise the possibility of marginal zone lymphomas or hairy cell leukemia (HCL). In some cases, these monocytoid-like cells may even expand to the marginal zone of lymphoid follicles, outside an apparently preserved mantle zone. CD5 and cyclin D1 positivity is crucial in the diagnosis of this variant.

Some occasional MCLs have a clonally related plasma cell component or a subpopulation of cells with lymphoplasmacytic differentiation including the presence of Dutcher bodies that may be confused with lymphoplasmacytic lymphoma (**Fig. 21-6**).[68-70] These tumors are cyclin D1 and t(11;14) positive but are SOX11 negative and seem to have a more indolent disease.

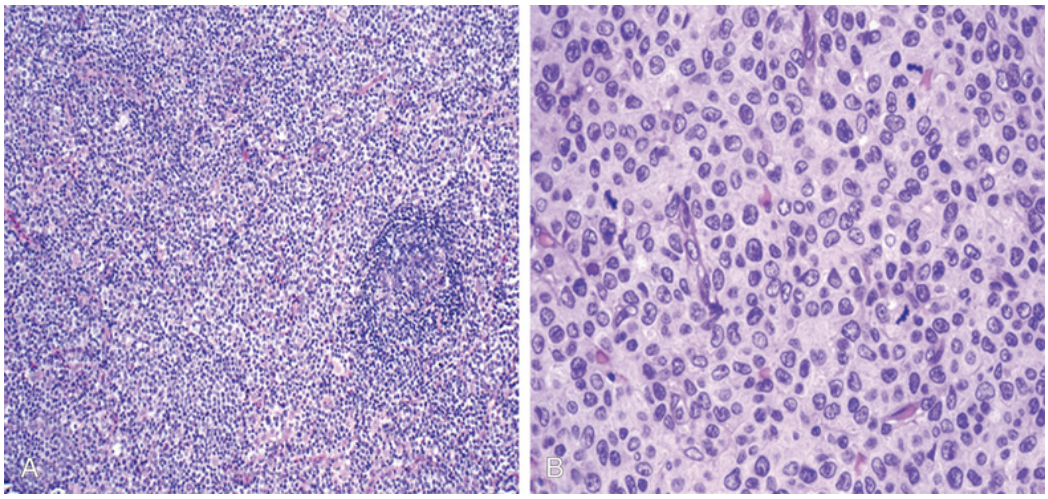

FIGURE 21-5 Mantle cell lymphoma with a marginal zone pattern.**A,** Tumor cells expand the marginal zone area outside an apparent preserved mantle cuff. **B,** Tumor cells in the marginal zone area have abundant pale cytoplasm, resembling monocytoid cells.

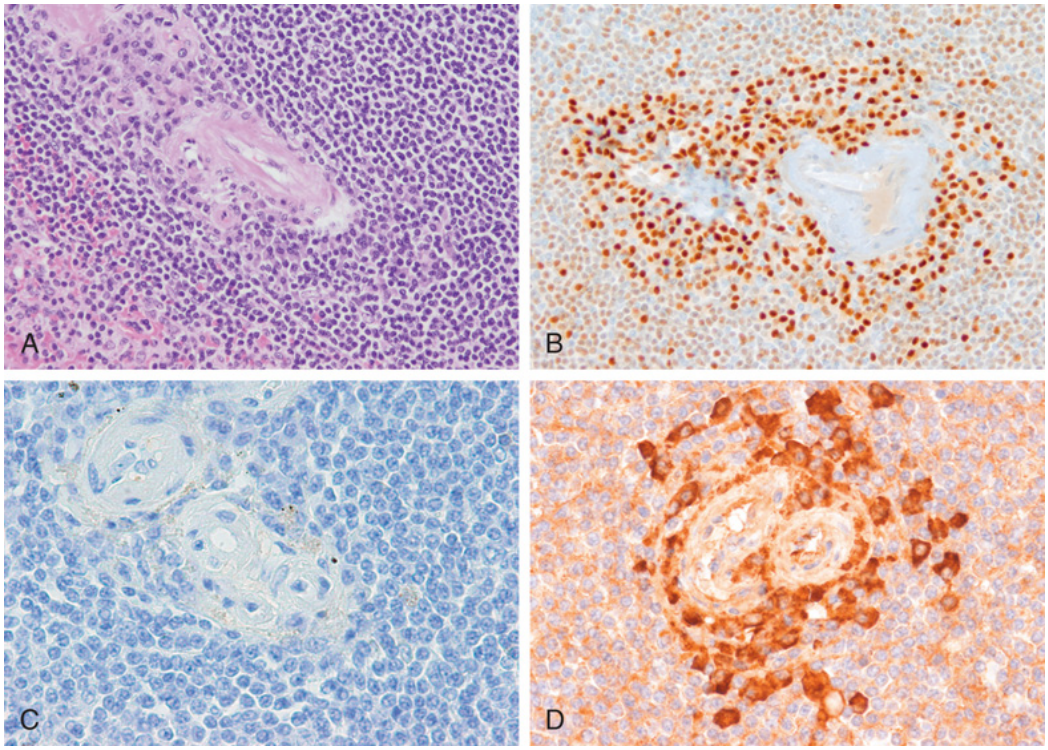

FIGURE 21-6 Mantle cell lymphoma with clonally related plasma cell differentiation.**A,** Splenic mantle cell lymphoma with perivascular plasma cell differentiation. **B,** Cyclin D1 is expressed both in the plasma cell component and in the small-cell component. The intensity of the staining is stronger in the plasma cells than in the atypical lymphoid cells. The plasma cells are negative for lambda **(C),** but positive for kappa **(D).** Case courtesy Dr. S. Serrano, Hospital del Mar, Barcelona, Spain.

Bone Marrow and Peripheral Blood

Bone marrow infiltration, independent of peripheral blood involvement, occurs in 50% to 91% of patients[15,25,26,29,36,39,71,72]

and is detected more frequently in core biopsies than in aspirates.[73] The pattern of infiltration may be nodular, interstitial, or paratrabecular, with most biopsies exhibiting a combination of these. Isolated paratrabecular aggregates are rare. In some cases, diffuse infiltration of the bone marrow may be seen. An intrasinusoidal pattern may be seen in some cases, mainly nnMCL (**Fig. 21-7**). The degree of infiltration does not seem to correlate with the histologic variants of MCL identified in lymph node biopsies, architectural patterns, or patient survival.[73] Immunohistochemical stains, including cyclin D1, can be used in the differential diagnosis of bone marrow biopsies to distinguish MCL from other small-cell lymphomas.[72,74] Dual staining of cyclin D1/CD79a and PAX5/CD5 may be useful for the detection of MCL in the marrow, particularly when there is a low-level or focal involvement.[75]

The cytologic appearance of tumor cells in peripheral blood and bone marrow aspirates is similar to the spectrum seen in tissues (**Fig. 21-8**). Circulating cells in most MCLs usually show a mixture of small-to-medium-sized cells with scant cytoplasm, prominent nuclear irregularities, and reticular chromatin. Some cells may have round nuclei, but the chromatin does not have the clumped appearance seen in CLL. Leukemic blastoid MCL may mimic acute leukemia, with medium-to-large-sized cells, a high nuclear-to-cytoplasmic ratio, finely dispersed chromatin, and relatively small or inconspicuous nucleoli.[42,44,76] These cases may have *MYC* rearrangements in addition to the *CCND1* translocation.[46,47,77,78] Some cases of leukemic MCL have very large atypical cells with prominent nucleoli that correspond to a leukemic phase of the pleomorphic variant with similar morphology in the lymph nodes.[63-

[66] Cases previously diagnosed as B-prolymphocytic leukemia carrying the t(11;14) translocation and cyclin D1 overexpression are now considered leukemic MCL.[79]

Spleen

Macroscopically, splenic involvement by MCL shows a generalized micronodular pattern that is occasionally associated with perivascular infiltration. Histologically, the differential diagnosis of MCL and other small-cell lymphomas in the spleen may be difficult.[80-82] White pulp nodules are enlarged, with variable involvement of the red pulp. Residual “naked” germinal centers are found in 50% of cases. Tumor cells show a similar monotonous morphology as in other locations. Interestingly, some cases may exhibit a marginal zone–like area at the periphery of the nodules, comprising cells with more abundant pale cytoplasm.[81]

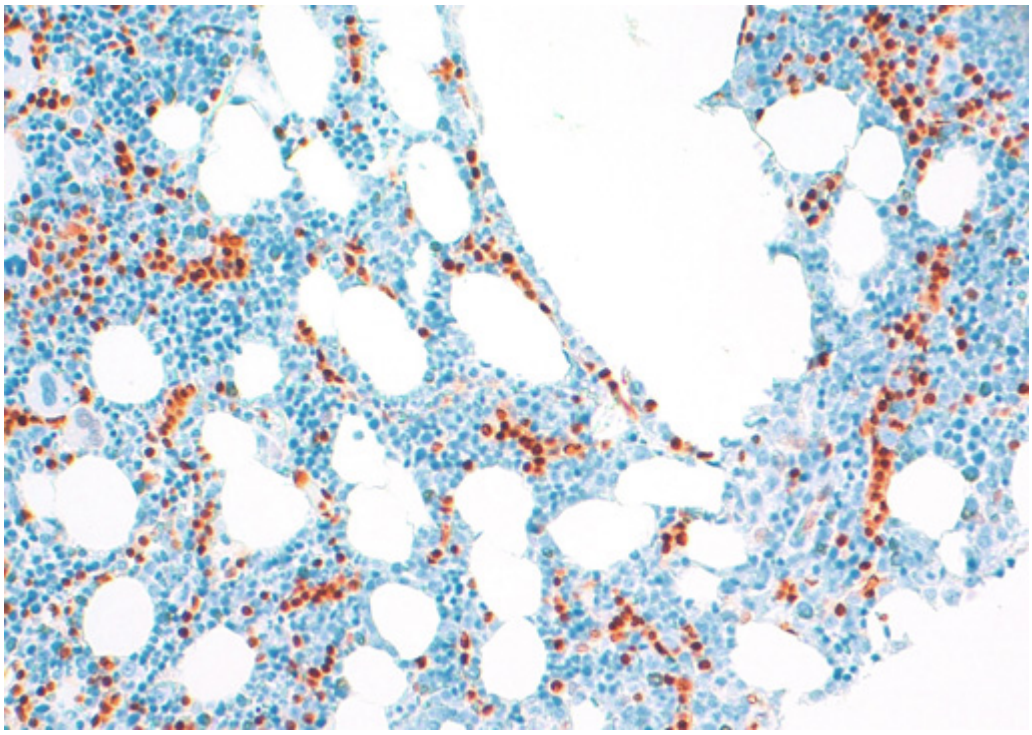

FIGURE 21-7 Cyclin D1 staining in a bone marrow biopsy highlights the intrasinusoidal infiltration by tumor cells of a leukemic non-nodal MCL.

Gastrointestinal Tract

A common manifestation of GI disease is lymphomatoid polyposis, in which multiple lymphoid polyps are identified in the small and large bowel (**Fig. 21-9**). These may be associated with large tumor masses, usually ileocecal, and regional lymphadenopathy.[30,31,83-86] Although this clinicopathologic presentation is relatively characteristic of MCL, it can also be caused by other lymphomas, particularly follicular lymphoma and marginal zone lymphoma of the mucosa-associated lymphoid tissue (MALT).[84,87] Cyclin D1 expression is useful for the differential diagnosis of these tumors.[83]

GI involvement without the macroscopic appearance of polyposis may also occur.[88] In these cases, superficial ulcers, large tumor masses, and diffuse thickening of the mucosa are common macroscopic findings. Routine gastroscopy and colonoscopy have identified MCL infiltration in up to 92% of patients.[85,89,90] Asymptomatic involvement of the GI tract with GI microscopic infiltration of endoscopically normal mucosa is very common (above 80%). However, these findings do not usually change the management decision.[85,89,90] In some cases, glandular infiltration by tumor cells may mimic lymphoepithelial lesions, making the distinction between MCL and marginal zone lymphomas difficult. However, the scarcity of these lesions and the monotonous character of the lymphoid infiltrate should suggest a diagnosis of MCL.[88] Interestingly, MCLs, and other lymphomas involving GI mucosa, express $\alpha_4\beta_7$-integrin, a homing receptor that binds to mucosal vascular addressin cell adhesion molecule 1 (MAdCAM-1), which is selectively expressed in endothelial cells of mucosa.[91]

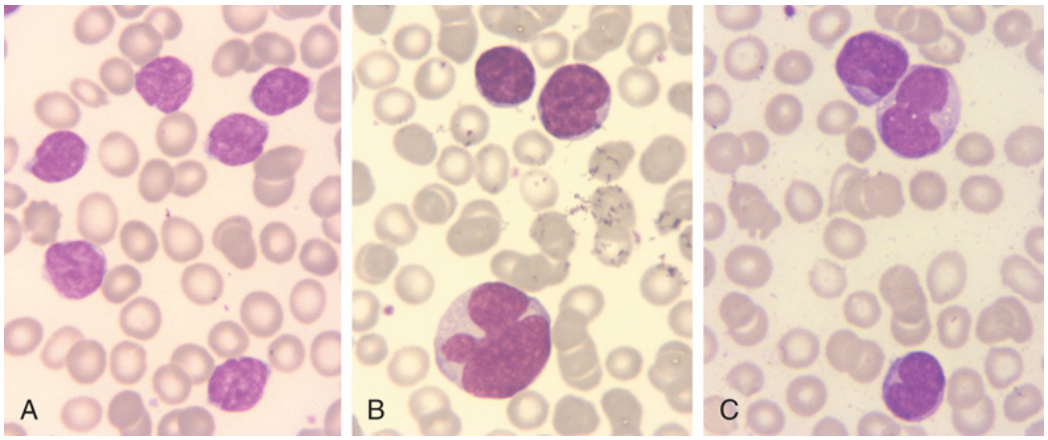

FIGURE 21-8 Cytologic spectrum of tumor cells in peripheral blood smears of leukemic mantle cell lymphoma.**A,** Classic variant with small lymphocytes, slightly indented or cleaved nuclei, condensed chromatin, and scant cytoplasm. **B,** Blastoid variant may show a mixture of small atypical cells and larger pleomorphic tumor cells with irregular nuclei. **C,** In other cases, all atypical cells have a more blastic morphology, with finely dispersed chromatin and inconspicuous nucleoli (Giemsa stain).

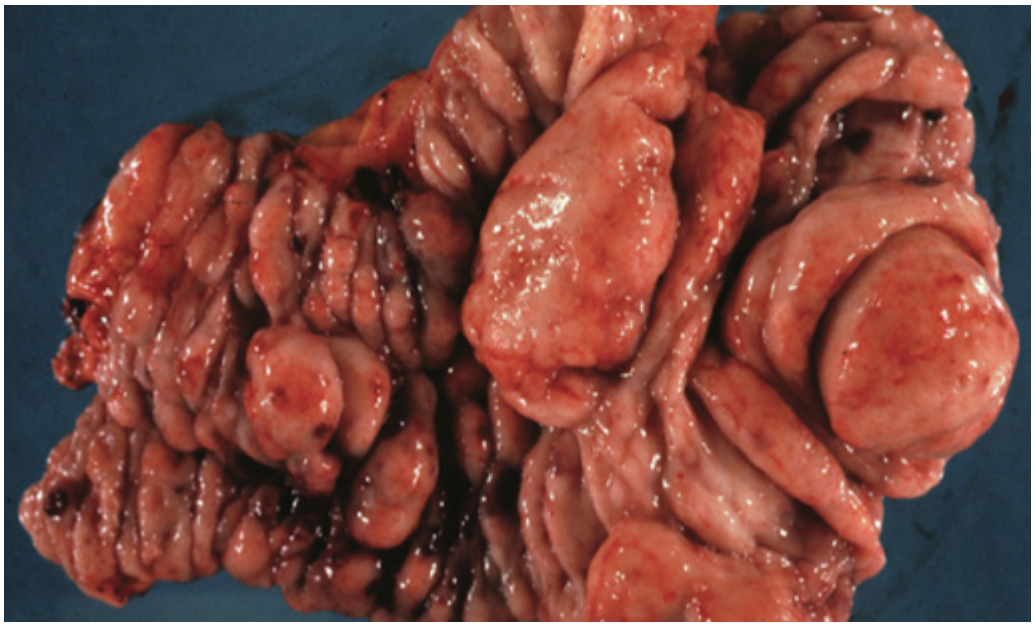

FIGURE 21-9 Mantle cell lymphoma involving the intestine with multiple lymphomatous polyposis. Courtesy Dr. T. Alvaro, Hospital Verge de la Cinta, Tortosa, Spain.

Histologic Progression

Sequential biopsies have shown that the histologic pattern of MCL remains relatively stable but progression from nodular to diffuse pattern and increased proliferation may be observed in serial biopsies.[34,57,92,93] Some cases may show an oscillating course, with changing patterns during the evolution of the disease.[94] Although most blastoid MCLs are detected already at diagnosis, around 20% to 35% of classic/small-cell variants may progress to a blastoid morphology in subsequent relapses and may be more common at autopsy than at diagnosis.[34,93-95] A clonal relationship has been demonstrated in the progression from classic to blastoid MCL.[96] Transformed blastoid MCLs display significant higher degree of

aneuploidy and poor outcomes compared with de novo blastoid variants.[97] On the other hand, 50% of MCLs with blastoid or pleomorphic cytology at primary diagnosis may relapse as a classic variant. In some cases, tumor progression is associated with the development of an overt leukemic phase.[41,42,44,76]

Composite Mantle Cell Lymphoma

MCL may be occasionally associated with a second lymphoid neoplasm at the same site, particularly follicular lymphoma, CLL/SLL, splenic and nodal marginal zone lymphomas, plasma cell neoplasms, and Hodgkin lymphoma.[93,98] Molecular studies have identified unrelated clonal rearrangements in most of these tumors, indicating distinct clonal origins but also the presence of common clone-specific IGH rearrangement in the MCL and the second lymphoma, suggesting the unusual evolution of a single malignant clone resulting in two morphologically, phenotypically, and molecularly distinct lymphomas.[99]

IMMUNOPHENOTYPE

MCL is a mature B-cell neoplasm expressing the B-cell markers CD19, CD20, CD21, PAX5, and CD79a (**Fig. 21-10**; **Table 21-3**). Surface immunoglobulins are usually of moderate to strong intensity, with frequent co-expression of immunoglobulin (Ig)M and IgD and a tendency to express lambda more frequently than kappa light chain (**Table 21-3**). The residual germinal centers seen in these tumors are always polyclonal. A peculiar characteristic of MCL is co-expression of the T cell–associated antigen CD5 in most cases (**Fig. 21-10**). However, CD5 negativity may be seen in MCL mainly with

small-cell morphology and SOX11 negativity.[100-102] CD43 is also frequently expressed, but other T-cell antigens are usually negative. CD8[103] and CD7[104] positivity by flow cytometry have been reported in isolated cases of MCL. Contrary to CLL, CD23 is usually negative but may be seen in indolent nnMCL[105,106] and rare cases of blastoid MCL.[105] CD200, an antigen usually expressed in CLL, is negative in most MCL,[106-108] although it may be positive in a subset of nnMCL.[49,50,109] CD10 and BCL6, two germinal-center cell markers, are usually negative, although occasional positive cases have been documented.[110-112] MCL with co-expression of CD10 and BCL6 are more likely to have bone marrow involvement, blastoid/pleomorphic morphology, higher Ki67 index, and complex cytogenetics with poor prognosis.[109,113] In these cases the differential diagnosis with diffuse large B-cell lymphoma carrying *CCND1* rearrangement as a secondary event has to be considered. LEF1, a transcription factor related to the WNT pathway, is expressed in the nucleus of CLL but not in other mature small B-cell lymphomas, including MCL, although some rare cases may be positive, particularly with blastoid or pleomorphic morphology.[114] LEF1 is also expressed in T cells and some large B-cell lymphomas including those transformed from small cells.[115,116] IRF4/MUM1 may be detected in around 50% of the tumors in at least a minor subset of cells.[69] The plasma cell–associated transcription factors BLIMP1 and XBP1 may be seen in around 50% and 30% of the cases, respectively, but they are significantly more frequently expressed in SOX11-negative MCL.[69] Some blastoid/pleomorphic MCL carrying *MYC* translocations may express terminal deoxynucleotidyl transferase (TdT). These cases are usually SOX11-positive.[47]

Overexpression of cyclin D1 is a constant and highly specific phenomenon in MCL that is very useful for the diagnosis (**Fig. 21-2**).[72,117,118] Current available antibodies, including rabbit monoclonal, provide consistent cyclin D1 staining.[119] In addition to immunohistochemistry, cyclin D1 overexpression may be detected by quantitative reverse transcription polymerase chain reaction that may be useful when routine immunohistochemistry cannot be easily applied, such as in leukemic lymphoproliferative disorders or fine-needle aspirates.[120,121] Cyclin D1 is always detected in the cell

nucleus, although the intensity may vary from cell to cell and case to case, probably reflecting parameters such as messenger RNA (mRNA) and protein stability. In some cases, extension to the cytoplasm may be seen. Cyclin D1 is also detected in the nuclei of histiocytes, endothelial cells, and epithelial cells, providing an important internal positive control. In addition to MCL, cyclin D1 is expressed in 25% of multiple myelomas with the t(11;14) translocation, amplification of the gene, or without apparent structural alterations of the gene.[122] Low levels of cyclin D1 are also detected in HCL,[123,124] and in cells of the proliferation centers in CLL, but this expression is not associated with the t(11;14) translocation in any of the two entities.[125] However, SOX11 may be expressed in HCL but not in the CLL proliferation centers.[126,127] Cyclin D1 expression has been identified in up to 15% of diffuse large B-cell lymphomas (DLBCLs) in which up to 80% of the cells may be positive. However, these cases are SOX11 negative and usually do not carry the t(11,14) translocation.[128-130] However, occasional DLBCL may express cyclin D1 with *CCND1* rearrangements.[131-133] The differential diagnosis of these cases may require additional genetic and molecular studies. The expression of cyclin D1 associated with copy number gains has been reported in mediastinal large B-cell lymphoma.[134]

Immunohistochemical detection of the cyclin-dependent kinase (CDK) inhibitor p27 is also useful in the differential diagnosis of MCL. Expression of p27 in lymphomas is usually inversely related to the proliferation activity of the cells. Thus it is strongly expressed in CLL, follicular lymphomas, and marginal zone lymphomas, but it is negative or weakly expressed in large-cell lymphomas. In MCL, p27

staining is independent of the proliferative rate and is usually negative or weaker than in the associated T cells in classic MCL and positive in blastoid variants.[135,136] HCL is also negative or very weakly positive.[74]

SOX11 is a neural transcription factor expressed in the nucleus of most MCLs, including blastoid and pleomorphic variants and cyclin D1–negative MCL (**Fig. 21-11**), but not in other mature B-cell lymphomas apart from weak expression in some Burkitt lymphomas. It is also expressed in T-lymphoblastic and B-lymphoblastic leukemias/lymphomas.[137,138] SOX11 is not expressed or very weak in the nnMCL subtype.[139] New monoclonal antibodies are useful for the recognition of this marker, although they have slightly different specificity and sensitivity. The monoclonal SOX11 antibody clone MRQ-58 (Cell Marque, Rocklin, CA) is highly specific but does not recognize cases with very low SOX11 expression. A meta-analysis evidenced that the MRQ-58 clone shows a robust performance to study SOX11 expression.[140] On the other hand, clone CLO143 (Atlas Antibodies) is more sensitive but cross-reacts with SOX4 and may be seen in some non-MCL cases.[141,142] The definition of guidelines in interlaboratory studies confirms that SOX11 status can reliably be assessed by IHC, also on decalcified tissue, either formalin or B5 fixed.[143,144] The measurement of SOX11 mRNA expression using RNAscope in situ hybridization is also a reliable method to detect SOX11 expression in MCL.[145]

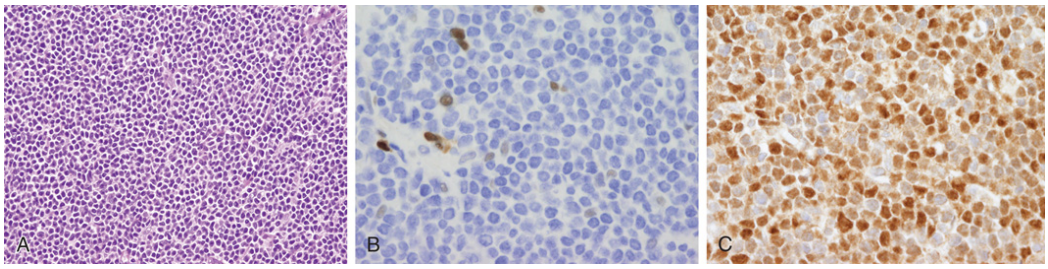

FIGURE 21-11 Cyclin D1–negative mantle cell lymphoma.**A,** Mantle cell lymphoma (MCL) with classic variant morphology. **B,** Cyclin D1–negative tumor cells. **C,** SOX11 is strongly positive in the nucleus of the tumor cells.

Ki67 staining is very relevant to define prognosis in MCL with a proposed cutoff of 30% defining more aggressive behavior.[143,146,147]

MCL usually contains a prominent meshwork of follicular dendritic cells, which are more variable in frequency and distribution in diffuse than in nodular cases. In nodular cases, two different patterns of follicular dendritic cells have been recognized. A dense and concentric meshwork of cells may represent colonization of preexisting follicular centers by tumor cells, whereas a loose and irregular pattern may correspond to expansion of primary follicles.[148] Cyclin D1 staining may identify early infiltration of germinal centers by tumor cells.

MANTLE CELL LYMPHOMA VARIANTS

Early Alterations and In Situ Mantle Cell Neoplasia

Cells carrying the t(11;14) translocation have been detected at very low levels with sensitive techniques in the blood of healthy

individuals (8%).[149] These clones can persist for long periods, but their potential to evolve into an overt lymphoma seems extremely low. However, the observation of a simultaneous MCL with the same clonal origin in recipients and donors many years after an allogenic bone marrow transplantation indicates that these clones may eventually progress to a full-blown tumor, and it may require a long latency period of up to 10 years.[150-152]

Cyclin D1–positive cells carrying the t(11;14) translocation have been incidentally found in the mantle zones of otherwise reactive lymphoid tissue in healthy individuals (**Fig. 21-12**).[153] These lesions were termed *in situ MCL*, but their malignant potential seems very limited, and the alternative term of *in situ mantle cell neoplasia (isMCN)* was proposed to avoid overtreatment. The cells are seen predominantly within the inner layers of the mantle cuffs of normal-appearing follicles with preserved lymph node architecture. In some cases, the cyclin D1–positive cells may occupy the mantle zone, but they are usually intermingled with negative lymphocytes, and the mantle is not expanded. In some cases, the positive cells may be seen in the center of the follicle. These lesions are uncommon and were not identified in more than 100 consecutive reactive lesions in two different studies.[153,154] The potential evolution to overt MCL has not been well studied but seems low. In one study, 1 of 12 of these lesions developed an overt MCL 4 years after its detection.[153] Retrospective analyses of reactive biopsies obtained in patients who subsequently developed MCL have identified isMCN or small extranodal MCL infiltrates antedating the diagnosis of MCL from 2 to 15 years, suggesting that MCL might have a long latency period.[154] In some patients, in situ lesions may be seen in different distant lymph

nodes.[153,155] Also, some patients with nodal isMCN may have clonal lymphocytosis with cyclin D1 expression.[153,156] None of these findings has been associated with progressive disease, and patients should be managed conservatively. Intriguingly, isMCN has also been found in association with other lymphoid neoplasias.[153] Most in situ lesions express SOX11, whereas few are SOX11 negative, suggesting that the in situ stage may be a common step in both SOX11-negative and SOX11-positive MCL subtypes.[153,157] By immunohistochemistry, these neoplastic cells are also positive for pan-B-cell markers, IgD, and BCL2. However, compared with cMCL, which usually expresses CD5 and CD43, isMCN is more frequently negative for these markers. Incidental in situ lesions have also been found in patients who are apparently in complete remission after treatment, suggesting that this microenvironment may sustain residual tumor cells resistant to chemotherapy.[153]

In situ MCN must be differentiated from early involvement by overt MCL with a mantle zone growth pattern. In these cases, the mantles are usually expanded and densely occupied by cyclin D1–positive cells that may focally extend to interfollicular areas. Images of back-to-back cyclin D1–positive mantle zones are commonly seen. This pattern correlates with progression to disseminated disease more frequently than in situ lesions.[153,154]

Leukemic Non-nodal Mantle Cell Lymphoma

Early studies identified a subset of MCL patients with a more indolent clinical behavior that presented clinically with a leukemic non-nodal disease associated in some cases with splenomegaly.[27,28] Subsequent studies have suggested that these tumors may

correspond to a specific subtype of MCL named nnMCL that is characterized by a leukemic phase with asymptomatic lymphocytosis persisting for a long time without requiring treatment. These patients may develop splenomegaly, and splenectomy may temporarily control the disease.[48,49,158-160]

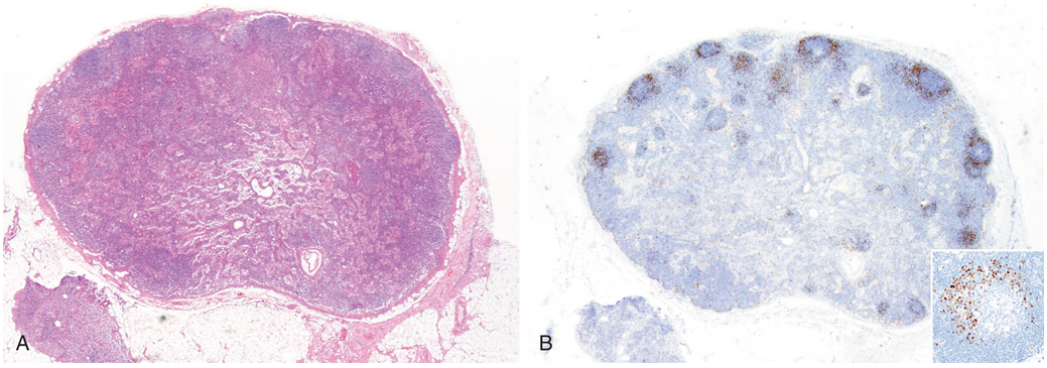

FIGURE 21-12 In situ mantle cell neoplasia.**A,** Reactive lymph node without morphologic evidence of mantle cell expansion. **B,** Cyclin D1 staining highlights the infiltration of the mantles of reactive lymphoid follicles by cyclin D1–positive cells. The positive cells are mainly present in the inner layers of the mantle, interspersed with negative lymphoid cells *(inset)*.

nnMCL frequently has a small-cell morphology, which makes differential diagnosis with CLL or other small B-cell lymphomas difficult. Phenotypically they may express CD200 and CD23, and around one-third are CD5 negative.[49,100,106] Contrary to cMCL, most of these tumors have mutated immunoglobulin heavy chain variable region genes (IGHV) and have simple karyotypes with no or very few chromosomal alterations in addition to the t(11;14)

translocation.[48,139] nnMCL and cMCL have marked differences in the gene expression of certain programs and they may be reliably distinguished by the expression of a 16-gene signature.[161] Among the differentially expressed genes is *SOX11* that is negative or very low in nnMCL.[48-50,109,139,158,162] cMCLs have a gene-expression profile closer to that of naïve B cells, whereas the profile of nnMCL is more similar to memory cells. Some SOX11-negative cases show morphologic and phenotypic plasmacytic differentiation (see **Fig. 21-6**).[69,70,163] Genome-wide sequencing studies have also shown some differences in the mutational landscape of cMCL and nnMCL. Some SOX11-negative MCLs have a blastoid/pleomorphic morphology, *TP53* mutations, and complex karyotypes, suggesting that they correspond to a progression of this disease.

Cyclin D1–Negative Mantle Cell Lymphoma

Some tumors with identical morphologic and phenotypic features as MCL are negative for cyclin D1 and the t(11;14) translocation. Some cases may show a mantle zone pattern or blastoid morphology.[164,165] SOX11 is highly expressed in cyclin D1–negative MCL and is a reliable tool to identify these tumors in clinical practice (**Fig. 21-11**).[137,140,144,145,164] The expression profile of these MCL is indistinguishable from that of cMCL.[166] These cases carry *CCND2* or *CCND3* translocations with IG genes, sometimes cryptic, including only the enhancer region of kappa or lambda genes inserted in the vicinity of these cyclin genes and can be detected by fluorescence in situ hybridization (FISH) probes.[164,167] Overexpression of these cyclins can be demonstrated by reverse-transcription quantitative PCR (RT-qPCR).[167,168] Immunohistochemistry is not useful in

routine practice because it is not discriminative enough to distinguish the high levels of these cyclins in MCL from their expression in other lymphoid neoplasms without the translocations.[137,164,167] Cyclin D1–negative MCLs have a clinical presentation similar to cyclin D1–positive cases, with frequent nodal and extranodal involvement and aggressive clinical behavior. The Ki67 proliferative index is also of prognostic significance. Genetic studies have detected a similar profile of secondary genetic alterations.[164] Rare MCLs may be cyclin D1 negative by immunohistochemistry but still carry the t(11;14). The negativity in these cases seems to be secondary to mutations or splicing alterations that eliminate the epitope recognized by common antibodies used in the clinics.[169]

CYTOGENETIC FINDINGS

The characteristic cytogenetic alteration in MCL is the t(11;14)(q13;q32) translocation but occasional translocation of 11q13 with the kappa and lambda loci in chromosomes 2 and 22 have also been reported.[170] These translocation are detected by conventional cytogenetics in up to 65% of MCLs. However, with FISH, they can be found in virtually all cases.[171-173] Break-apart probes for *CCND1* may detect cases in which this gene is not translocated to the IGH and they are recommended for routine practice.[70] The t(11;14) translocation has been identified in 20% of multiple myelomas.[8,174] In addition, cyclin D1 gene amplification without translocation has been documented in cases of multiple myeloma and DLBCL but not in MCL.[122,131,132] *CCND1* rearrangement can be seen in occasional

DLBCL and in the progression of small B-cell neoplasms as a secondary event.[133,175]

Cytogenetic studies, including conventional analysis, FISH, comparative genomic hybridization, and array-based analysis, have revealed a high number of secondary chromosomal alterations in MCL that target genes involved in proliferation, DNA damage, and cell survival pathways (**Table 21-4**).[77] The most common secondary alterations are losses of chromosomes 1p, 6q, 8p, 9p, 10p, 11q, 13q, and 17p and gains in 3q, 7p, 8q, 12q, and 18q. Blastoid variants have more complex karyotypes and high-level DNA amplifications than classic variants.[43-45,61,62,97,176] In addition, certain chromosomal imbalances such as gains of 3q, 7p, and 12q and losses of 17p are significantly more frequent in blastoid than classic variants. Tetraploidy is more frequent in pleomorphic (80%) and blastoid (36%) variants than in classic MCLs (8%).[62] Chromosome 8q24 alterations, including the t(8;14)(q24;q32) translocation and variants, have been identified in occasional blastoid MCLs with a very aggressive clinical course.[45,46,177] Copy neutral loss of heterozygosity is an alternative mechanism for the inactivation of mutated tumor suppressor genes such as *TP53* at 17p13.[178] Complex genome alterations including chromoplexy, chromothripsis, and breakage-fusion-bridge (BFB) cycles are more frequently in aggressive cMCL variants.[61,179]

MOLECULAR CHARACTERISTICS

Translocation (11;14) and Cyclin D1 Expression

The t(11;14) translocation juxtaposes the immunoglobulin heavy chain joining region in chromosome 14 to a broad region on 11q13 designated B-cell lymphoma/leukemia 1 (BCL1). Most rearrangements (30% to 55%) occur in a region known as the *major translocation cluster (MTC)*, whereas up to 10% to 20% of cases may have breakpoints in other distal regions. The MTC breakpoints occur within a relatively small region of around 80 base pairs on chromosome 11 and in the 5′ area of one of the Ig JH regions on chromosome 14, making it possible to detect by PCR techniques.[180]

The target gene of this translocation is *CCND1,* located approximately 120 kb downstream of the BCL1 translocation locus. This translocation occurs at the pro-B stage of differentiation during the recombination of the V(D)J segments of the IGH variable region in the bone marrow. IG breaks are mediated by recombination-activating genes (RAG enzymes) and mainly occur in IGHD and

IGHJ genes, likely during the initial D-J recombination. However, in a small subset of cases the t(11;14) seems to occur in mature B stage during somatic hypermutation or class switch recombination mediated by activation-induced cytidine deaminase (AID) machinery.[179] *CCND1* translocation to the immunoglobulin light chain genes are uncommon.[77] Cryptic translocations of IG, particularly insertions of IGK and IGL enhancers near *CCND1,* have been reported.[181,182]

Cyclin D1 is not normally expressed in lymphocytes or myeloid cells, but it is constantly expressed in MCLs.[117,118,120,121] Tumor cells express two major mRNA transcripts of 4.5 and 1.5 kb that contain the whole coding region of the gene and differ only in the length of the 3′ untranslated region. Some MCLs express truncated transcripts at the 3′ untranslated region that are more stable and show very high levels of expression caused by the loss of AUUUA destabilizing sequences of the 3′ region.[117,118] These truncated messages are generated by second chromosomal rearrangements or point mutations at the 3′ region of the gene.[170,174,183-186] These secondary events in the 3′ region of *CCND1* may be important in disease progression. Gains and amplifications of the translocated allele have been observed in some tumors that also have high levels of cyclin D1 expression.[178] A frequent polymorphism of exon 4 may generate a splicing isoform (cyclin D1b) missing exon 5 that may be differentially expressed but does not seem to be relevant in MCL pathogenesis.[187-190]

In addition to the truncations of the 3′ UTR, *CCND1* is frequently mutated in the 5′ region, particularly in nnMCL, because of the activity of AID.[97,179,191-194] Recurrent coding mutations in the first

exon of cyclin D1 have been associated with the stabilization of cyclin D1 protein and increased resistance of MCL cell lines to ibrutinib.[195] These mutations seem to be caused by AID. The adoption of all these different mechanisms by MCL cells to increase the levels of cyclin D1 mRNA expression reinforces the relevance of *CCND1* in MCL lymphomagenesis and suggests a dose-dependent oncogenic effect.

Cyclin D1 Oncogenic Mechanisms

Cyclin D1 functions as a weak oncogene in animal models, cooperating with other oncogenes, generally *MYC* and *RAS,* or with frequent deregulated tumor suppressor genes (TSGs), including *ATM* and *BIM,* although their transforming mechanisms are not well understood.[196-198] Cyclin D1 participates in the control of the G_1 phase by binding to CDK4 and CDK6. The complexes phosphorylate retinoblastoma protein, leading to the inactivation of its suppressor effect on cell cycle progression and the release of important transcription factors, such as E2F, that participate in the regulation of other genes involved in cell cycle.[199] *RB1* may be inactivated by truncating mutations in occasional MCL, reinforcing the role of this checkpoint in the pathogenesis of these tumors.[200]

MCL may also have impaired control of late G_1 phase and G_1 phase to S phase transition. This step is regulated by the cyclin E–CDK2 complex and the cyclin kinase inhibitor p27 *(CDKN1B)*. In classic MCL, p27 immunohistochemical detection is negative or weak, but it is paradoxically positive in blastic variants. No structural alterations of the *CDKN1B* gene have been found, and low detection of the protein may be caused by increased protein degradation by the proteasome pathway[201] or sequestration by the overexpressed cyclin

D1, rendering it inaccessible to antibody detection.[202] p27 inhibits the complexes between CDK2 and cyclin E at the end of the G_1 phase. Increased degradation or blocking of p27 by cyclin D1 releases the activation of these complexes and allows the cell to progress to the following cell-cycle phases.[135] All these observations indicate that cyclin D1 deregulation plays an important role in the development of MCL, probably overcoming the suppressive effect of retinoblastoma protein and p27 (**Fig. 21-13**). Besides these mechanisms, cyclin D1 may have an important oncogenic potential independent of its catalytic function by acting as a transcriptional modulator of multiple genes or participating in the DNA damage response pathway.[203-207] However, whether these mechanisms participate in the MCL pathogenesis is not yet known.

SOX11 Oncogenic Mechanisms

SOX11 is a transcriptional factor physiologically involved in neural organogenesis and is highly expressed in cMCL, including cyclin D1 negative variants, but not in nnMCL.[137,164,208] SOX11 promotes tumor growth of MCL cells in vivo and regulates a broad transcriptional program that includes B-cell differentiation, proliferation, apoptosis, angiogenesis, motility, invasion, and BCR signaling (**Fig. 21-13**).[209] SOX11 may contribute to MCL pathogenesis blocking B-cell differentiation forcing PAX5 expression and impairing its necessary downmodulation for B cells to differentiate to plasma cells.[163] SOX11 also represses BCL6 expression that may prevent cells from entering the germinal center.[210] SOX11 may increase cell survival by enhancing BCR signaling.[211] SOX11 also promotes the aggressiveness of MCL cells

regulating their interactions with the microenvironment inducing angiogenesis through PDGFA, tumor cell migration, adhesion, and cell proliferation by CXCR4 and FAK, and modulating an immunosuppressive microenvironment characterized by CD70 overexpression in tumor cells and increased Treg cell infiltration. The lack of SOX11 in nnMCL may explain the long period of these cases with a leukemic phase without nodal involvement because they have less angiogenic and tumor invasion capacity.[49,139,158,212-215]

Despite the relevant role of SOX11 in MCL, the mechanisms leading to its specific upregulation in this lymphoma are not well understood. Studies have identified an active distant super enhancer that interacts with the promoter in SOX11 expressing tumors.[216,217] Some evidence suggests that *STAT3* and *CCND1* may act as a transcriptional repressor and positive regulator of SOX11, respectively.[218]

Molecular and Genomic Profile

In addition to cyclin D1 deregulation as the primary oncogenic event, genetic and molecular studies have identified other alterations that are important mechanisms in disease progression. These gene alterations particularly involve cell cycle, DNA damage response, and cell survival pathways, among others.[219-221] Whole-genome/whole-exome sequencing (WGS/WES) studies have confirmed the relevance of these pathways and identified new mutated genes that might be clinically and biologically relevant (**Table 21-5**).[97,179,191-194,222]

Cell Cycle Deregulation

Highly proliferative and clinically aggressive MCLs carry oncogenic alterations in two major regulatory pathways that are involved in cell-cycle control and senescence: CDKN2A-CDK4-RB1 and ARF-MDM2-TP53. Homozygous deletions of the *CDKN2A* locus on 9p21 have been detected in 20% to 30% of blastoid variants but in less than 5% of typical cases.[56,223,224] Inactivation of other members of the *CDKN2* family, such as *CDKN1B, CDKN2B,* and *CDKN2C,* are less frequent.[178,179] *CDK4* amplification and inactivating mutations of *RB1* in some aggressive blastoid MCLs strengthens the significance of the deregulation of the G_1-to-S transition in MCL progression.[200,225] *TP53* mutations are rarely observed in classic low-proliferative MCL, but they are identified in approximately 30% of highly proliferative blastoid MCL, usually associated with a 17p deletion.[61,179] Concomitant alterations in *TP53* and *CDKN2A-CDK4-RB1* may have an additive prognostic effect independent of the Ki67 index.[223-225]

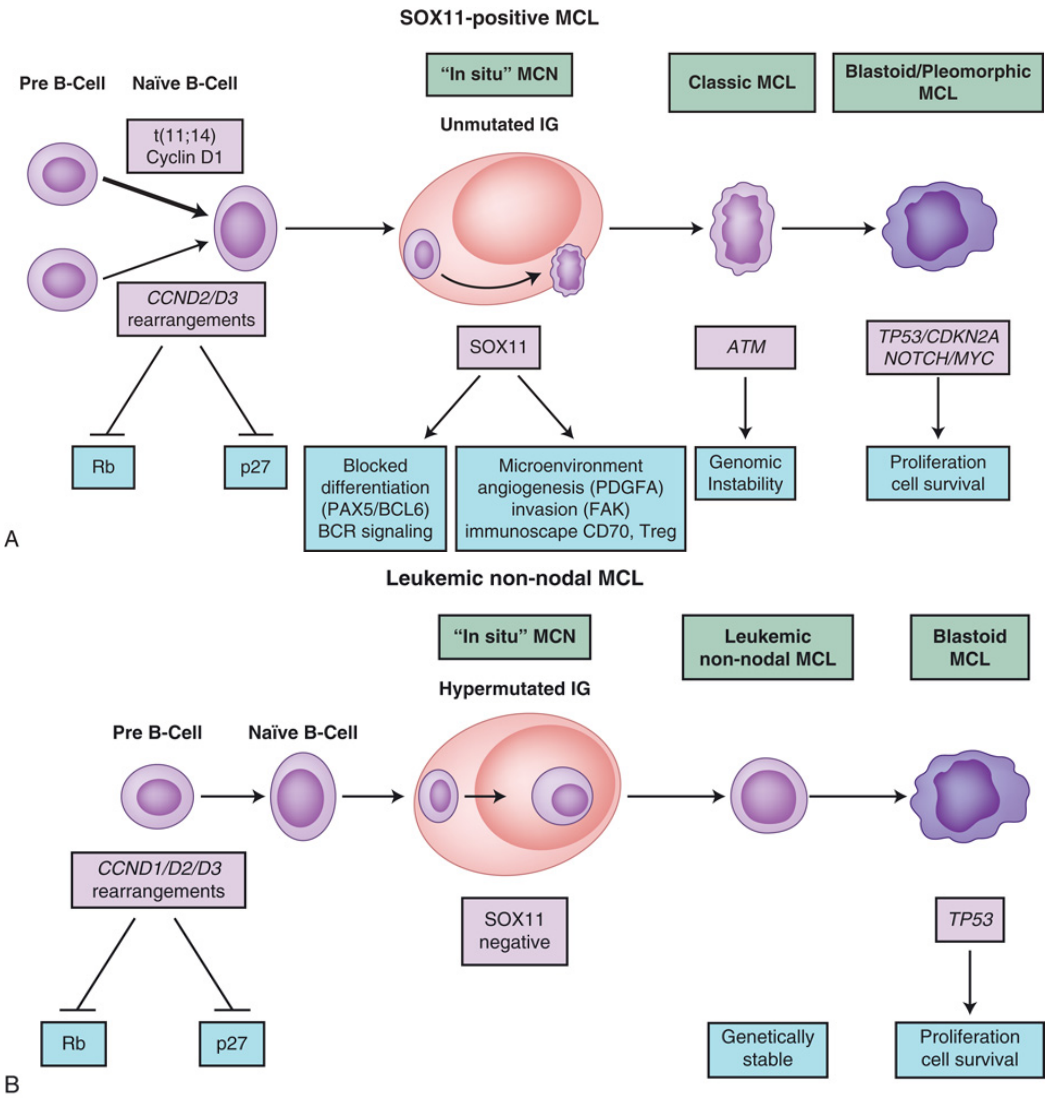

FIGURE 21-13 Proposed model of molecular pathogenesis of two subtypes of mantle cell lymphoma (MCL), SOX11-positive MCL **(A)** and leukemic non-nodal SOX11-negative subtypes **(B)**. **A,** The t(11;14) translocation occurs in an immature B cell and leads to the constitutive deregulation of cyclin D1 and early expansion of tumor B cells in the mantle zone areas of lymphoid follicles in both subtypes. Rare cases that are negative for the t(11;14) translocation

carry *CCND2* or *CCND3* rearrangements and are SOX11 positive. SOX11-positive MCLs usually have unmutated immunoglobulin variable region heavy chain (IGHV) and may be derived from cells with no influence of the germinal-center microenvironment. These tumors acquire frequent ataxia-telangiectasia mutated *(ATM)* mutations that may facilitate the development of additional genetic alterations and expansion of MCL cells with a classic morphology. Increased genomic instability may target genes in the cell-cycle and cell-survival pathways that lead to more aggressive variants. **B,** Leukemic non-nodal MCLs carry hypermutated IGHV and may be derived from a cell with germinal-center experience. These tumors are genetically stable, persist with a leukemic phase for long periods, and may develop splenomegaly. Subsequent acquisition of additional genetic alterations may lead to transformation of the disease. *MCN,* Mantle cell neoplasia.

DNA Damage Response Pathway

One of the most frequent genetic aberrations in MCL is the deletion of 11q22.3, including the *ATM* gene, which plays an important role in the DNA damage response pathway. *ATM* mutations have been detected in 34% to 48% of MCLs (**Fig. 21-13**).[226-229] WES analysis has confirmed *ATM* as the most frequently mutated gene in MCL and

present exclusively in cMCL, in which it may be found in more than 70% of the cases, but is absent in nnMCL.[97,179,191] Occasional patients carry an *ATM* mutation in the germline.[228,229] *CHK2,* a putative tumor suppressor gene located downstream of *ATM,* also may be involved in MCL pathogenesis by protein downregulation and occasional germline mutations. Recently *SAMHD1,* involved in DNA replication and DNA damage response, has been described as a new driver gene in MCL[179] and associated with in vitro resistance to nucleoside analogues in patient-derived MCL cells.[230]

Cell Survival and Other Pathways

Additional molecular events that deregulate survival and apoptosis mechanisms seem to contribute to MCL oncogenesis. Particularly, amplification and overexpression of BCL2 and homozygous deletion of the pro-apoptotic *BIM* gene have been described in MCL cell lines and primary tumors.[178,231] In addition, cyclin D1 itself seems to sequester the pro-apoptotic protein BAX, facilitating the anti-apoptotic effect of BCL2.[232]

Activating mutations in different genes of the nuclear factor-κB (NF-κB) and BCR pathways has been observed including *TRAF2* (5%), *NFKBIE* (5%), *BIRC3* (5%–10%), *BCOR* (5%), and *CARD11* (5%) and have been related to ibrutinib resistance.[179,191,194,233] Activating mutations of *NOTCH1* and *NOTCH2* are seen in 4% to 14% of MCLs, usually with blastoid morphology and aggressive behavior.[97,179,191,222,234] Mutations affecting chromatin modifier genes such as *KMT2D* (14%–23%), *NSD2* (7%–8%), and *MEF2B* (5%–8%) also occur frequently in MCL. Other recurrent mutations

occur in *HNRNPH1* (5%–10%), involved in RNA regulation, and *UBR5* (5%–10%) in ubiquitination mechanisms.[179,194]

Table 21-5

* Targeted mainly by deletion or amplifications.

† More frequently reported in nnMCL.

Mutations in Mantle Cell Lymphoma Subgroups

Sequencing analysis of specific subgroups has shown frequent mutations of *NOTCH2, NOTCH3,* and *UBR5* in blastoid/pleomorphic MCL (**Fig. 21-13**).[97] *MYC* translocations have been rarely reported in MCL, but almost all cases had blastoid or pleomorphic morphology, leukemic expression, complex karyotypes, and a very aggressive clinical course with a short survival of 2 to 10 months.[46,47,77,235] In one study, relapsed MCLs carry more frequent 9p21 deletions (64%) than tumors at diagnosis (38%). Comparison of the genomic profile between cMCL and nnMCL is still limited.[179,191] cMCLs carry significantly higher numbers of structured variants, copy number alterations, and driver alterations than nnMCLs. Most mutated genes are more common in cMCL than nnMCL, with the exception of *TP53* alterations that are more frequent in nnMCL (35%–70% versus 15%–20%).[145,179] *CCND1* 5′ mutations, *TERT* alterations, and activating *TLR2* mutations have been predominantly found in SOX11-negative tumors.[179,191]

POSTULATED CELL OF ORIGIN

The normal counterpart of MCL may be heterogeneous corresponding to different subsets of mature B-cell expressing CD5. Owing to the distribution of tumor cells in the mantle cuff and the positivity for alkaline phosphatase, early studies suggested a relationship between this tumor and cells of the primary lymphoid follicle or the mantle cells of secondary follicles.[236] CD5 expression in MCL is very high, resembling the intensity observed in fetal B cells, in contrast to the low levels detected in the subset of adult follicular mantle cells.[237] In that sense, the CD5-positive fetal-derived lymphocytes B1a have been postulated as putative cell of origin for MCL.[238] The presence of few or no somatic mutations in IGHV genes in most MCL supports a relationship to cells that have not experienced the follicular germinal-center cells. Intermediate cells between naïve and germinal-center cells, or transitional B cells already expressing AID, have been suggested as the cell of origin of cMCL.[239,240] However, somatic hypermutations are detected in 15% to 40% of MCLs, indicating that some tumors originate in cells that have passed through the germinal center. The load of IGHV mutations is related to the molecular subtype of MCL since most cMCLs have no or few mutations, whereas nnMCLs carry hypermutated IGHV, suggesting that they may originate in different subpopulations of B cells.[27,100] This idea was confirmed by DNA methylation studies that show the relationship of cMCL with naïve-like B cells, whereas nnMCL seemed derived from memory-like cells.[216] A biased use of the IGHV4-34, IGHV3-21, IGHV1-8, and IGHV3-23 genes has been detected in MCL. Around 10% of all MCLs have stereotyped heavy complementary-determining region 3 (VH CDR3) sequences. These findings strongly suggest that antigen

selection plays an important role in the pathogenesis of at least a subset of MCL.[241-243]

MULTISTEP DEVELOPMENT OF MANTLE CELL LYMPHOMA

The development of MCL may follow different steps, which are important to understand in order to adjust the management of the patients to the biological significance of these alterations.[244] The identification of the nnMCL subtype clinically and biologically different from the conventional SOX11-positive MCL suggests two major genetic and molecular pathways in the pathogenesis of these tumors (see **Fig. 21-13**). In both subtypes, the t(11;14) translocation occurs in an immature B cell in the bone marrow, which leads to the constitutive deregulation of cyclin D1 and early expansion of tumor B cells in the mantle zone areas of lymphoid follicles. Rare cases that are negative for the t(11;14) translocation carry *CCND2* or *CCND3* translocations and are SOX11 positive. Overexpression of these G1 cyclins may initiate the development of MCL by overcoming the cell-cycle suppressor effect of retinoblastoma and p27. SOX11-positive MCL usually has unmutated IGHV and may be derived from cells that have not experienced the influence of the germinal-center microenvironment. SOX11 overexpression may contribute to the subsequent development of the tumors by blocking the terminal B-cell differentiation forcing the expression of PAX5 and preventing its downregulation required for the plasma cell differentiation. In addition, SOX11 promotes the expression of the angiogenic factor PDGFA, facilitating the infiltration of tissues by tumor cells. The frequent *ATM* mutations facilitate the development of additional

genetic alterations, increased genomic instability, and further alterations in cell-cycle and cell-survival regulatory genes, which leads to more aggressive variants of MCL.

nnMCLs carry hypermutated IGHV and may derive from a cell with germinal-center experience. These tumors are genetically stable, persist with a leukemic phase for long periods, and may develop splenomegaly. Subsequent acquisition of additional genetic alterations such as *TP53* inactivation may lead to transformation of the disease.

Clinical Course

The clinical behavior of MCL is very heterogeneous, with some patients following a very rapid fatal evolution in less than 1 year, whereas approximately 10% may survive over 10 years. This variability may be in part explained by the two MCL subtypes, with cMCL being more aggressive than nnMCL, and cytologic variants in which blastoid/pleomorphic MCL confer a dismal prognosis.[10,59] The survival of MCL patients is improving over the years, particularly with new therapeutic strategies. Median overall survival (OS) has expanded from less than 3 to more than 6 years (**Fig. 21-14**).[245,246] Most patients with cMCL have complete initial responses but they are relative short with conventional therapeutic regimens, although maintenance strategies after induction are improving outcomes. After relapse, patients may experience a relatively slow course for several months, with enlargement of lymph nodes and increased resistance to chemotherapy; this is followed by a more rapid and progressive evolution in a final accelerated phase. Although the initial clinical presentation of blastoid/pleomorphic

variants is relatively like that of classic MCL, the clinical evolution is much more aggressive. Patients have a poor response to therapy and usually fail to obtain complete remission, which is associated with a rapid clinical course and death from progressive disease. In patients with complete remission, the duration of the response is usually short, and virtually all patients relapse in less than 1 year.[59,97]

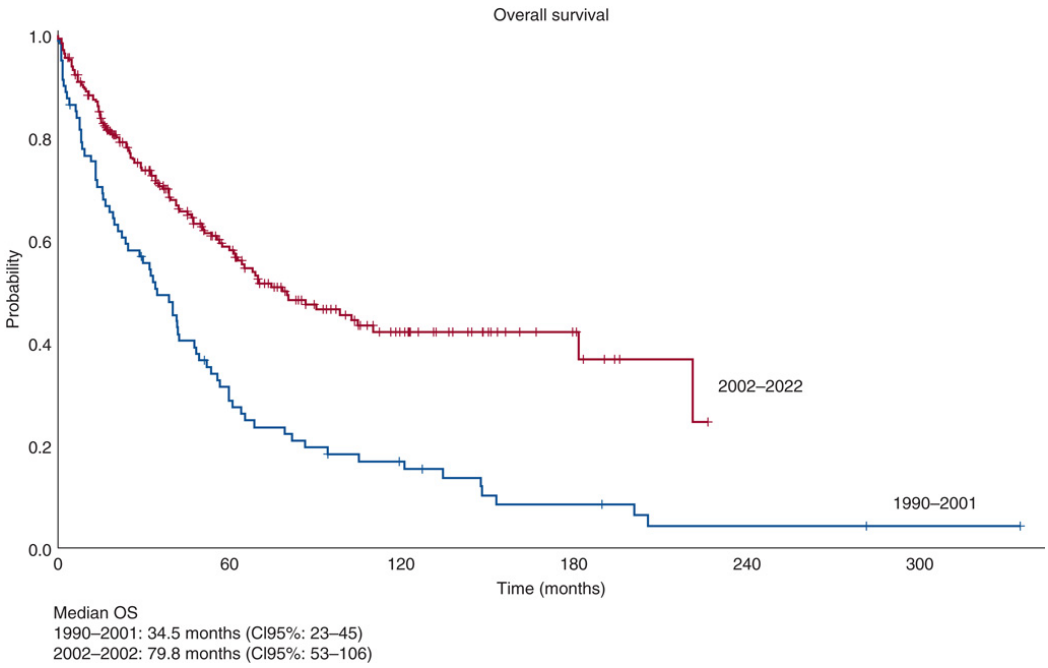

FIGURE 21-14 Overall survival of patients with mantle cell lymphoma has improved, with a median increase from 3 to more than 6 years. Although some long-survival patients have been identified, there is no survival plateau in this type of lymphoma. Courtesy Dr. E. Gine and Dr. A. Lopez-Guillermo, Hospital Clinic de Barcelona, Barcelona, Spain.

Indolent Mantle Cell Lymphoma

Different studies have recognized a subset of MCL patients who do not require treatment at diagnosis and may be maintained under a "watch and wait" approach for long periods without detriment to their OS.[247,248] These patients with deferral treatment usually have stable disease for several months, stage I/II, good performance status, no B symptoms, normal LDH levels, and no or limited nodal presentation than patients receiving early treatment.[249-251] Intriguingly, the proliferation index, one of the best biological indicators of aggressive behavior in MCL, was not able to predict the time to the need of treatment in one of these studies.[251] Interestingly, p53 protein overexpression and non-nodal presentation were associated with shorter and longer time, respectively, to the need of treatment.[249-251]

The pathologic and biological substrates of these clinically indolent MCL are not well known. Some patients may have an early stage or initial MCL characterized by an in situ neoplasm or MCL with a mantle zone pattern.[252] Some cases may correspond to cMCL with a very low proliferative index[253] or they may correspond to the nnMCL subtype. In a clinical trial designed to treat patients with an indolent MCL (stable disease for at least 3 months, no or limited lymphadenopathy <3 cm, good performance status, Ki67 <30%, and no blastoid/pleomorphic morphology), 45% of cases were biologically cMCL and 55% nnMCL. *TP53* mutations and complex karyotypes (≥3) were detected in 15% and 41% of the patients, respectively, suggesting that these biological factors are not sufficient to explain initial indolent behavior of the disease, although the disease progressed earlier in patients with *TP53* mutations.[254] There

are no biological markers validated that may help differentiate between those patients who would benefit by immediate treatment and those who could be expectantly observed. Therefore pathology information should be combined with clinical features of the patients to decide the best management strategy.

PROGNOSTIC PARAMETERS

Clinical and analytical prognostic parameters of adverse evolution currently used in the clinics are older age, poor performance status, advanced stage of disease (Ann Arbor Stage III or IV), splenomegaly, anemia, and high serum levels of b2-microglobulin and LDH.[255]

The proliferative activity is the most important biological prognostic factor in MCL, independent of the method used for its evaluation, mitosis, Ki67 immunostaining, proliferation signature by gene expression profiling, or others.[253] A high proliferative index recognized by Ki67 immunostaining (≥30% of positive tumor cells) has adverse prognosis, and has been validated in randomized trials (**Fig. 21-15**).[147] Although high proliferation is associated with blastoid morphology, tumors with classic cytology may also have high proliferative activity and a rapid clinical course. Reproducibility among pathologists of Ki67 assessment has difficulties. Recommendations have been proposed that include assessment of a minimum count of five independent high-power fields or two manual counts of 100 cells each in separated representative areas, avoidance of residual germinal centers, hot spots of proliferation, and proliferating T cells, among others.[143,146] However, the concordance between different labs defining low and high Ki67 index with the 30% cutoff was 65% in one study.[143] A limitation of the Ki67 index is

the need of tissue and it cannot be performed in purely leukemic patients. A gene signature composed of 17 genes associated with proliferation (MCL35 assay) stratifies patients in high-risk (26%), standard-risk (29%), and low-risk (45%) groups, with median OS of 1.1, 2.6, and 8.6 years, respectively. This assay can use RNA extracted from routine formalin fixed paraffin embedded tissue, is highly reproducibly among laboratories, and its prognostic value has been confirmed in different clinical trials.[256-259] Morphologic prognostic parameters associated with worse outcome are the diffuse pattern and blastoid/pleomorphic variants, but they are not independent of the Ki67 index.[147]

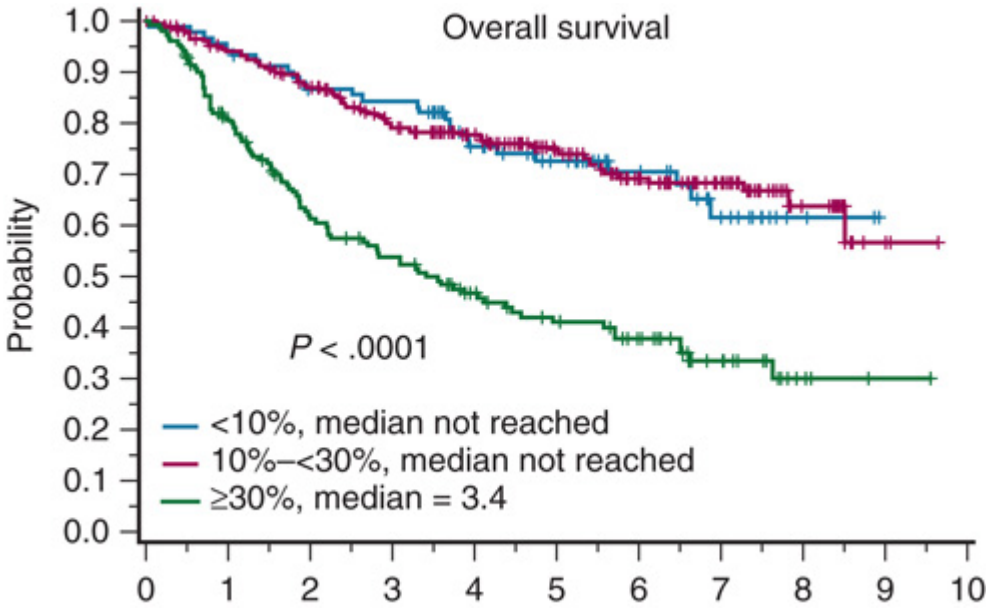

FIGURE 21-15 Overall survival and Ki67 proliferative index in mantle cell lymphoma.Highly proliferative tumors (>30%) had a worse prognosis than those with a lower proliferative index in the context of randomized clinical trials with high-dose immunochemotherapy. From Hoster E, Rosenwald A, Berger F, et al. Prognostic value of Ki-67 index, cytology, and growth pattern in mantle-cell lymphoma: results from randomized trials of the European Mantle Cell Lymphoma Network. J Clin Oncol. 2016;34:1386-1394.

The MIPI is based on four independent prognostic factors (age, Eastern Cooperative Oncology Group [ECOG] performance, LDH count, and leukocyte count) that stratify MCL patients into three groups with low-risk (44% of patients, median OS not reached), intermediate-risk (35%, 51 months), and high-risk groups (21%, 29

months), and its value has been confirmed in randomized trials.[260] The incorporation of the Ki67 index in the MIPI as a biological parameter (MIPIb)[253] or combining MIPI and Ki67 (MIPIc) improves the power of its prediction stratifying patients in four prognostic groups of low, low-intermediate, high-intermediate, and high risk with median OS of 9.4, 4.9, 3.2, and 1.8 years.[147]

The main prognostic genetic alterations are *TP53, CDKN2A* inactivation, and *MYC* amplification/rearrangement. The value of *TP53* and *CDKN2A* have been confirmed in clinical trials.[161,224,261,262] Tumors with complex karyotypes (≥3 alterations) have a more aggressive course.[176,263] *TP53* and *MYC* alterations may have prognostic value independent of genomic complexity.[179] A DNA methylation-based mitotic clock, named epiCMIT (epigenetically determined cumulative mitoses), able to capture the proliferative history of B-cell tumor samples has shown independent prognostic value in MCL.[179]

The minimum residual disease (MRD) analysis, based in the evaluation of circulating residual lymphoma cells, using high sensitivity and specificity methods, has shown prognosis value in MCL and may be a parameter that may guide therapy, particularly with new agents.[254] A meta-analysis has confirmed the use of MRD levels as a prognostic marker during the treatment and management of MCL patients.[264]

THERAPY

The management of MCL has changed owing to stratification of the patients according to stage, age, and, particularly, the fitness of the patients.[255] Some patients may be eligible for a “wait and see” policy

for a long period.[249,250] In localized cases without additional risk factors, a shortened immunochemotherapy followed by a consolidating radiotherapy is considered appropriate. For young, fit patients with advanced disease requiring treatment, the introduction of immunotherapy with cytarabine-based regimens in different strategies (and usually consolidated with autologous transplant) has produced a remarkable improvement in survival, with a progression-free survival rate of 70% at 6 years. Rituximab maintenance after this treatment is currently considered for younger patients. Lenalidomide is also of benefit but only in patients not eligible for rituximab.[255] Less-intense regimens are proposed for patients that cannot tolerate these regimens, including immunotherapy combined with different chemotherapy regimens and rituximab maintenance.[255] No standard therapies have been proposed after relapse. Molecular targeted therapies are increasingly used, including Bruton tyrosine kinase inhibitors, BCL2 inhibitors, and lenalidomide among other options, whereas new molecular-targeted combinations and immunotherapeutic approaches are being explored in different trials, opening new perspectives for these patients. Allogenic stem cell transplant could be considered, but the introduction of chimeric antigen receptor T-cell (CART) therapy with very remarkable results in relapsed and refractory MCL patients will probably displace it to further lines in the therapeutic algorithm. On the other side of the spectrum, a clinical trial in patients with indolent MCL has shown that a non-chemotherapy regimen with ibrutinib and rituximab may obtain complete clinical and molecular (minimal residual disease) responses in more than 80% of the patients and 69% of the patients could discontinue ibrutinib after 2 years because of undetectable

MRD. *TP53* mutations were associated with progression of the disease.[254]

DIFFERENTIAL DIAGNOSIS

Benign Disorders

Several lymphoid hyperplastic conditions may resemble MCL. In particular, expanded primary lymphoid follicles and mantle zone hyperplasias seen in reactive lymph nodes or associated with Castleman disease may suggest MCL with nodular or mantle zone patterns, respectively.[54,265] In these reactive conditions, lymphoid cells usually lack the nuclear irregularities observed in MCL, the nodal architecture is relatively preserved, and the clinical presentation is localized lymphadenopathy in a young patient. Although CD5 may be positive in some Castleman disease cases,[266] in most other situations its negativity together with SOX11 and cyclin D1 negativity, as well as lack of monoclonality, rules out the diagnosis of MCL.

Cyclin D1–Negative Mantle Cell Lymphoma

In the case of a small B-cell lymphoma that resembles MCL but in which cyclin D1 is negative, the differential diagnosis is difficult and may encompass three situations: (1) cMCL in which the apparent cyclin D1 negativity is caused by technical immunohistochemical failure or to mutations in *CCND1*, rendering the protein inaccessible to antibodies, (2) true cyclin D1–negative MCL, and (3) other small B-cell lymphomas morphologically and phenotypically mimicking MCL. To rule out the first situation, it is important to investigate the presence of *CCND1* rearrangements by FISH or assess the cyclin D1

expression by other methods such as RT-qPCR. Recognition of the cyclin D1–negative MCL is facilitated by SOX11 expression. SOX11 should be studied in small B-cell lymphomas with monotonous atypical cells, particularly if they are CD5 positive.[137] Given the important clinical effect of the diagnosis of MCL, these cyclin D1–negative MCLs must be identified with great caution. When both cyclin D1 and SOX11 are negative, other small B-cell lymphomas must be considered. However, rare cases of small B-cell lymphomas that mimic MCL and are negative for these two markers and *CCND1/D2/D3* translocations are occasionally seen and are difficult to classify. In these cases, a diagnosis of small B-cell lymphoma, unclassifiable, may be justified.

Atypical Leukemic Lymphoid Neoplasms

Some cases of MCL may present with atypical lymphocytosis without the morphology (round cells) or phenotype (CD5 negative, CD23 positive) suggestive of MCL. Some of these patients may have splenomegaly without peripheral lymphadenopathy, and they may be difficult to diagnose if cytogenetic or molecular studies of the peripheral blood are not performed.[27] Cyclin D1 and SOX11 expression by RT-qPCR should be performed to rule out MCL. Previous cases defined as B-prolymphocytic leukemia with the t(11;14) translocation are now considered MCL, particularly pleomorphic variants.[79,267]

Chronic Lymphocytic Leukemia–Small Lymphocytic Lymphoma

Some CLLs may have a high number of lymphocytes with “cleaved,” irregular nuclei, mimicking MCL.[268] In addition, CLL/SLL in lymph nodes may present with a predominant interfollicular pattern surrounding reactive secondary follicles. The tumor cells may even infiltrate the mantle zone, creating “naked” germinal centers without an apparent mantle cuff, as is frequently seen in MCL. The predominance of small cells with round nuclei and the presence of prolymphocytes and paraimmunoblasts with central nucleoli, either isolated or in small aggregates, help in the diagnosis of CLL/SLL because these features are always absent in MCL (**Table 21-6**). Cyclin D1 and SOX11 expression should facilitate the diagnosis of MCL, whereas LEF1 positivity would support the diagnosis of CLL/SLL (**Table 21-3**).

Table 21-6

CLL/SLL, Chronic lymphocytic leukemia–small lymphocytic lymphoma; *DLBCL,* diffuse large B-cell lymphoma; *FL,* follicular lymphoma; *MCL,* mantle cell lymphoma; *MZL,* marginal zone lymphoma, *TdT,* terminal deoxynucleotidyl transferase.

* Immunophenotype, cyclin D1, and SOX11 expression are major differential characteristics.

Follicular Lymphoma

Differentiating nodular MCL from follicular lymphoma is one of the most common problems (**Table 21-6**). Some cases of MCL have a striking nodular pattern, suggestive of follicular lymphoma. The monotonous cell population, with a lack of centroblasts and slightly

fewer nuclear irregularities, should raise the possibility of MCL. However, occasional centroblasts representing cells from residual germinal centers may render the diagnosis of MCL difficult. Immunohistochemical staining for CD5, cyclin D1, SOX11, CD10, and BCL6 typically provides the diagnosis (**Table 21-3**). The differential diagnosis between follicular lymphoma with a diffuse pattern and diffuse MCL may also be difficult on histologic grounds, but it should be resolved by immunophenotyping. The diagnosis of follicular lymphoma with a diffuse pattern requires the presence of a minority of centroblasts and a typical follicular center cell phenotype with expression of CD10, BCL2, and BCL6. These cases usually are CD23 positive and carry *STAT6* mutations not seen in MCL.[269]

Marginal Zone Lymphoma

Some cases of MCL may have tumor cells with relatively abundant pale cytoplasm, which, coupled with the presence of residual germinal centers, may suggest a diagnosis of marginal zone lymphoma.[67] The identification of areas of classic MCL and the absence of a mantle cell corona surrounding reactive germinal centers would suggest a diagnosis of MCL (see **Table 21-6**). However, in some blastoid MCLs with pale cytoplasm, the tumor cells surrounding the germinal centers may be smaller, mimicking a residual mantle cell cuff. The immunophenotype and molecular characteristics of MCL, with CD5 cyclin D1 and SOX11 expression, should confirm the diagnosis of MCL. It is important to recognize these tumors as MCL because their behavior is aggressive, with extensive dissemination and a rapid clinical course. Some previously described cases of aggressive CD5-positive marginal zone lymphoma

may correspond to these MCL variants.[270] Mutational profile may be of help in the differential diagnosis.

Diffuse Large B-Cell Lymphoma

Pleomorphic MCL is sometimes confused with large B-cell lymphoma (**Fig. 21-16**; **Table 21-6**). The large size of the cells and the occasional presence of a nucleolus may suggest this diagnosis. CD5, SOX11, and cyclin D1 detection facilitates the diagnosis of MCL. However, CD5 and cyclin D1 may be expressed in some DLBCLs. These cases usually are SOX11 negative and do not carry *CCND1* rearrangement,[128] but some cases also carry this *CCND1* rearrangement. In these cases the presence of *BCL2* translocations or detection of a mutational profile of diffuse large B-cell lymphoma may assist in the differential diagnosis with true MCL.[133]

Acute Leukemias

Blastoid MCL may present as a leukemic disorder with a very aggressive clinical course, mimicking acute myeloid or lymphoblastic leukemia (**Table 21-6**). Clinically, these cases may represent evolution of a preexisting nodal disease,[271] or the leukemic expression may be the initial manifestation of disease.[44] These cases express the typical MCL phenotype with strong mature B-cell markers, surface immunoglobulins, cyclin D1, and CD5. Terminal deoxynucleotidyl transferase may be positive in some of these cases although CD34 should be negative.[47] Cytogenetics and molecular studies may demonstrate the t(11;14) translocation.

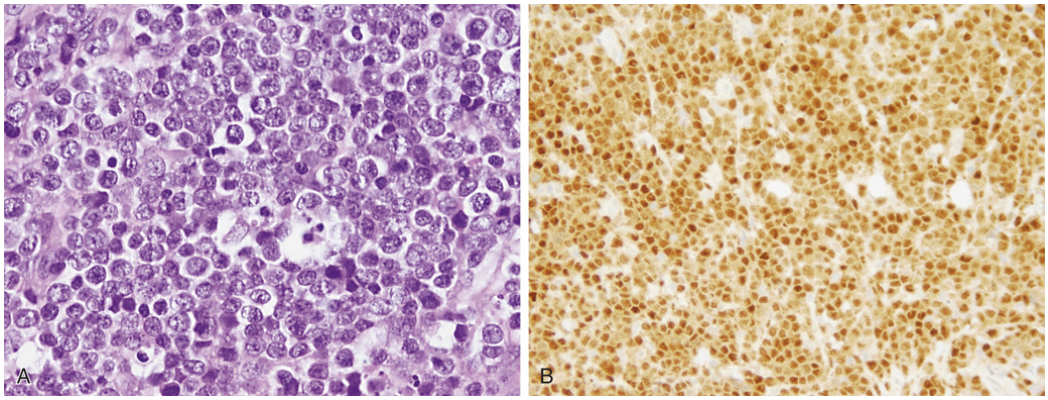

FIGURE 21-16 Diffuse large B-cell lymphoma with t(11;14) translocation and cyclin D1 overexpression. A, Diffuse large B-cell lymphoma. **B,** Cyclin D1 staining shows strong staining in virtually all tumor cells. The tumor was negative for CD5 and SOX11, but carried *CCND1* rearrangements detected by fluorescence in situ hybridization. Genomic sequencing detected a profile of mutations uncommon in mantle cell lymphoma and frequent in diffuse large B-cell lymphoma.

Pearls and Pitfalls

- Mantle cell lymphoma (MCL) is characterized by a monotonous proliferation of small-to-intermediate-sized lymphoid cells with irregular nuclei, a mature B-cell phenotype co-expressing CD5, and the genetic t(11;14) translocation leading to the overexpression of cyclin D1.

- Some tumors may present with small-cell, blastoid, pleomorphic, or marginal zone–like morphologic variants, mimicking other mature B-cell neoplasms such as chronic lymphocytic leukemia, acute leukemia, diffuse large B-cell lymphoma, or marginal zone lymphoma, respectively.
- The phenotype of MCL—expressing mature B-cell markers, SOX11, and CD5, but negative for CD23, BCL6, and CD10—is highly suggestive of the disease. However, some cases may have aberrant phenotypes lacking CD5 or expressing CD23, CD200, CD10, or BCL6. Cyclin D1 overexpression and the presence of the t(11;14) translocation are key elements in the diagnosis.
- Leukemic non-nodal MCL is a distinct molecular and clinical subtype of MCL that also has *CCDN1* rearrangement and overexpression. Cells may express CD23, CD200, and be negative for CD5. These cases may have a stable disease for a long period.
- Occasional cyclin D1–negative MCLs have been recognized. The transcription factor SOX11 is a useful marker for the diagnosis of MCL, including the cyclin D1–negative variant.
- The clinical behavior of MCL is usually aggressive. The tumor's proliferation is considered the most important biological parameter for predicting tumor behavior.
- MCL patients with a relatively indolent clinical course in whom the prognosis is not impaired by deferring initial treatment have been recognized. These patients are usually asymptomatic and present with leukemic non-nodal disease.

INTRODUCTION

Diffuse large B-cell lymphoma (DLBCL) is a mature aggressive B-cell lymphoma, which has been progressively split into more discrete large B-cell lymphoma entities. The main group, DLBCL, not otherwise specified (DLBCL, NOS) has been further subdivided based on phenotypic and genotypic features. This chapter will cover DLBCL, NOS, its subtypes, and the other distinct large B-cell lymphomas with stricter definitions (**Box 22-1**). Most likely additional studies will continue to identify specific subgroups within DLBCL, NOS, which will become distinct diseases in future classification systems. In this chapter, terminology use includes both the International Consensus Classification of Mature Lymphoid Neoplasms (ICC) and the proposed 5th edition of the World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues (WHO HAEM5). Where terminology or diagnostic criteria diverge, these differences are briefly explained.

DEFINITIONS, SYNONYMS, AND TERMS

In the most basic sense, DLBCL, NOS and other large B-cell lymphomas (LBCL) consist of diffuse proliferations of large-or-medium-sized neoplastic, immunophenotypically mature, monoclonal B cells with a nuclear size greater than or equal to that of a histiocyte nucleus, or more than twice the size of a small lymphocyte (**Fig. 22-1**).[1] DLBCL, NOS is the name given to cases not conforming to one of the more specifically defined subtypes covered in this chapter and elsewhere.[2] **Table 22-1** contains a list of synonyms and terms of the various entities discussed in this chapter. High-grade B-cell lymphomas (HGBLs), viral-associated lymphomas, and lymphoproliferative disorders associated with immunodeficiency (including posttransplant lymphoproliferative disorders) are discussed in detail in their respective chapters.

DIFFUSE LARGE B-CELL LYMPHOMA, NOT OTHERWISE SPECIFIED

Definition

DLBCL, NOS is a lymphoma composed of large-sized B cells in a diffuse growth pattern. By definition a diagnosis of exclusion, the defining features of other entities specified within the ICC and WHO HAEM5 need to be sought before arriving at this diagnosis. This includes consideration of the anatomic site of disease (DLBCL of the central nervous system [CNS], DLBCL of the testis, **Chapter 59**, and DLBCL of the skin, leg type, **Chapter 19**), Epstein-Barr virus (EBV) status of the tumor cells (EBV+ DLBCL, **Chapter 28**), the clinical

history (immune deficiency and dysregulation, including history of transplant, **Chapter 54**), and presence of concurrent chromosomal rearrangements (HGBL-*MYC/BCL2* and HGBL-*MYC/BCL6*, **Chapter 23**).

Epidemiology

DLBCL, NOS is the most common type of non-Hodgkin lymphoma, accounting for 31% of all cases according to an international multicenter study.[3] A United States–based evaluation of lymphoma epidemiology confirmed DLBCL, NOS as the most frequent lymphoid neoplasm overall at an incidence of 6.9 cases per 100,000.[4] Non-Hispanic Whites and males have a higher incidence of DLBCL, NOS compared with other racial, ethnic, and sex groupings. The slight male predominance over females is estimated at 1.49:1.[3,4] In Asians, DLBCL, NOS accounts for a higher percentage of all non-Hodgkin lymphomas than in the United States and Western Europe (>40%), most likely explained by a lower incidence of follicular lymphoma (FL) in these populations.[4-6] Any age can be affected; however, DLBCL is much more common in adults.[4,7,8] The median age of the patients is 64 years.[3] The overall trend in incidence for DLBCL, NOS has been fairly stable since 2001 in both men and women.[4]

Box 22-1 Diffuse Large B-Cell Lymphoma, Not Otherwise Specified, Variants, Subtypes, and Other Large B-Cell Lymphomas

ALK, Anaplastic lymphoma kinase; *EBV,* Epstein-Barr virus; *HHV-8,* human herpesvirus 8.

DLBCL, Not Otherwise Specified

- Morphologic variants
  - Centroblastic
  - Immunoblastic
  - Anaplastic
  - Other rare variants
- Gene expression (cell-of-origin) subtypes
  - Germinal center B-cell–like (GCB)
  - Activated B-cell–like (ABC)

Other Lymphomas of Large B-Cells

- T-cell/histiocyte–rich large B-cell lymphoma
- Large B-cell lymphomas of immune-privileged sites including primary DLBCL of the central nervous system or primary DLBCL of the testis (see **Chapter 59**)
- Primary cutaneous DLBCL, leg type (see **Chapter 19**)
- EBV^+ DLBCL, NOS (see **Chapter 28**)
- Large B-cell lymphoma with *IRF4* rearrangement (see **Chapter 17**)
- Primary mediastinal large B-cell lymphoma
- Intravascular large B-cell lymphoma
- DLBCL associated with chronic inflammation (see **Chapter 28**)

- HHV-8 and EBV-negative primary effusion-based lymphoma (ICC) also known as fluid overload-associated B-cell lymphoma (WHO-HAEM5)
- Lymphomatoid granulomatosis (see **Chapter 28**)
- ALK^+ large B-cell lymphoma (see **Chapter 24**)
- Plasmablastic lymphoma (see **Chapter 24**)
- HHV-8–positive diffuse large B-cell lymphoma (see **Chapter 28**)
- Primary effusion lymphoma (see **Chapter 28**)

High-Grade B-Cell Lymphoma

- Diffuse large/high-grade B-cell lymphoma, with *MYC* and *BCL2* rearrangements (see **Chapter 23**)
- High-grade B-cell lymphoma, with *MYC* and *BCL6* rearrangements (provisional, see **Chapter 23**)
- High-grade B-cell lymphoma, NOS (see **Chapter 23**)

Mediastinal Gray-Zone Lymphoma (see **Chapter 27**)

Etiology

Suspected risk factors in adults with DLBCL, NOS and other LBCL include autoimmune diseases that involve B-cell activation, hepatitis C virus seropositivity, farming occupation, and higher body mass index as a young adult.[4]

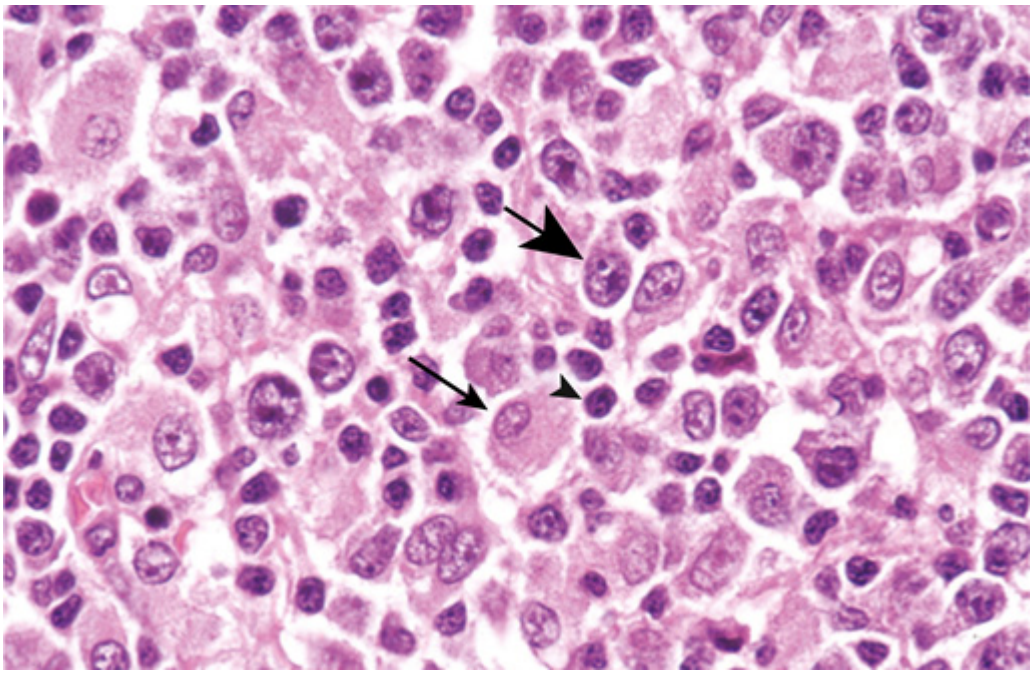

FIGURE 22-1 Diffuse large B-cell lymphoma: nuclear size assessment.In this example with numerous admixed histiocytes and lymphocytes, the interspersed histiocytes (with abundant eosinophilic cytoplasm) can conveniently be used as internal biological "rulers" for measuring the size of lymphoma cells. The lymphoma cells *(large arrow)* are considered large because their nuclei are slightly larger than those of the histiocytes *(small arrow)*. The neoplastic cells are more than twice the size of the small lymphocytes *(arrowhead)*.

A minority of cases occur in the setting of congenital, acquired, or iatrogenic immunodeficiency or immune perturbation (such as in angioimmunoblastic T-cell lymphoma).[9,10] EBV-positive DLBCL, NOS (formerly EBV-positive DLBCL of the elderly), which occurs in

patients without evidence of overt immunodeficiency, is believed to result from the subtle immunologic deterioration that occurs as part of the aging process.[11,12] Rare extranodal LBCL are associated with chronic inflammation or irritation, such as postmastectomy lymphedema,[13] chronic suppurative inflammation in bone and skin,[14] previous surgery and metallic implants,[15,16] juxta-articular soft tissues in long-standing rheumatoid arthritis,[17] and long-standing pyothorax.[18] Many of these cases are associated with EBV and are covered in the chapter on virally associated B-cell lymphoproliferative disease (see **Chapter 28**).[19] A rare, but newly defined, entity is the human herpesvirus 8 (HHV-8) and EBV-negative primary effusion-based lymphoma, which overlaps with fluid overload–associated lymphoma. The latter terminology allows for a minority of cases which are HHV-8 negative but EBV positive.[20,21] These lymphomas occur in older patients who are generally human immunodeficiency virus (HIV) negative, may have hepatitis C, and have a medical condition leading to fluid overload, such as renal, cardiac, or liver disease.[22,23]

* Discussed in follicular lymphoma chapter.

Most DLBCL, NOS and LBCL arise de novo, but some cases transform from an underlying low-grade lymphoma such as FL

(which may harbor *BCL2* and *MYC* rearrangements), chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), lymphoplasmacytic lymphoma (LPL), marginal zone lymphoma (MZL), extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT) lymphoma, or nodular lymphocyte–predominant B-cell lymphoma (NLPBL). Rare cases of DLBCL, NOS occur synchronously or metachronously with classic Hodgkin lymphoma (CHL).[1]

Clinical Features

Most patients present with rapidly enlarging lymph nodes or tumor masses in extranodal sites. About 30% of cases present in extranodal sites, and 71% have extranodal involvement during the course of the disease.[1] Common primary extranodal sites include the gastrointestinal tract (especially the stomach) and Waldeyer's ring, but practically any organ can be involved, including the skin, CNS, mediastinum, and bone.[1] Extranodal lymphomas of specific sites, especially of the skin, CNS, and testes, show distinctive clinical and biological features (see **Chapters 19 and 59**).

Approximately 30% of patients present with limited-stage (nonbulky and anatomically localized stage I to II without systemic symptoms) disease,[24] and one-third have B symptoms.[25] Bone marrow involvement occurs in 16%,[25,26] with concordant or discordant histology observed in equal proportions.

Morphology

Involved lymph nodes or tissues show complete or partial effacement of architecture by diffuse infiltrates of lymphoma cells, often with

coagulative necrosis and permeation into the surrounding tissues (**Fig. 22-2**). Uncommonly, the lymphoma shows an interfollicular or sinusoidal pattern of nodal involvement (see **Fig. 22-2**; **Box 22-2**). More rarely, tumor cells may form deceptively cohesive nodules, mimicking carcinoma (see **Fig. 22-3**). There may be necrosis, cell debris, and frequent mitoses, particularly in cases with high proliferation rates. However, these findings do not automatically place a case into the HGBL category (**Fig. 22-4**). In highly proliferative cases of DLBCL, NOS, close microscopic inspection is needed to determine that one of the typical DLBCL cytologies is present and there is no evidence of a genetic "double hit" (see **Chapter 23**). Background sclerosis may be present, especially in mediastinal and retroperitoneal tumors (**Fig. 22-5**). In the case of transformation, the lymph nodes may show evidence of the preexisting low-grade lymphoma (**Fig. 22-6**).

At extranodal sites, in addition to forming tumor masses, the lymphoma cells commonly infiltrate in an interstitial pattern, resulting in wide separation and loss of the normal specialized structures, such as between gastric glands, salivary acini, seminiferous tubules, thyroid follicles, connective tissue, or epithelium (causing mucosal ulceration) (**Fig. 22-7**). An intravascular pattern should raise the differential of intravascular large B-cell lymphoma (IVLBCL).

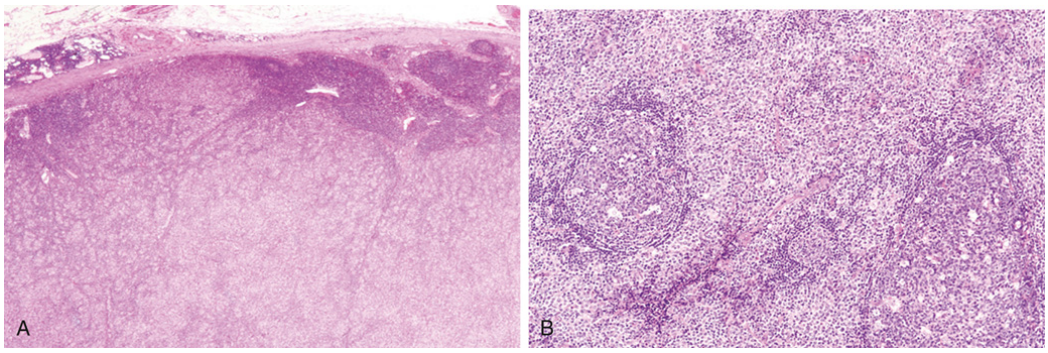

FIGURE 22-2 Nodal diffuse large B-cell lymphoma.**A,** The lymph node architecture is effaced by a diffuse lymphomatous infiltrate, with spillover into the perinodal tissue *(upper-left field)*. Some residual lymph node tissue is seen *(upper right field)*. **B,** In this example, the lymphoma selectively involves the interfollicular zone, mimicking reactive lymphoid hyperplasia. Features supportive of a diagnosis of lymphoma include erosion of the mantles of the reactive follicles and a monotonous interfollicular cellular infiltrate.

Box 22-2 Differential Diagnoses of Large-Cell Neoplasms With a Prominent Sinusoidal Pattern of Nodal Involvement

ALK, Anaplastic lymphoma kinase; *DLBCL,* diffuse large B-cell lymphoma; *NOS,* not otherwise specified.

- DLBCL
    - ALK-positive large B-cell lymphoma

- DLBCL, NOS (uncommon)
- ALK-positive anaplastic large cell lymphoma
- ALK-negative anaplastic large cell lymphoma
- Histiocytic neoplasms or tumor like conditions
  - Langerhans cell histiocytosis
  - Rosai-Dorfman-Destombes disease
  - Histiocytic sarcoma (uncommon)
- Metastatic non-hematolymphoid malignancies (e.g., melanoma, carcinoma, germ-cell tumor)

Cytologically, DLBCL, NOS is most commonly comprised of large-to-medium-sized lymphoid cells with the morphologic features of centroblasts (large noncleaved cells) or immunoblasts. Centroblasts have round to oval vesicular nuclei, multiple membrane-bound small basophilic nucleoli, and a thin rim of amphophilic cytoplasm (**Fig. 22-8**). Immunoblasts have round or oval vesicular nuclei, a single large, centrally located, usually eosinophilic nucleolus, and a broad rim of basophilic cytoplasm (**Fig. 22-9**). The immunoblasts sometimes exhibit plasmacytoid features, with eccentrically located nuclei and paranuclear hofs. The lymphoma cells may not always conform to these classic cell types, exhibiting hybrid features of centroblasts and immunoblasts (see **Fig. 22-9**).[1] Lymphomas with greater than 90% immunoblasts are considered the *immunoblastic variant,* whereas those with less than 90% immunoblasts are considered the *centroblastic variant*.[27] Cytologic subclassification of DLBCL, NOS into centroblastic or immunoblastic subtypes is optional for current diagnosis. Rarely, DLBCL, NOS and LBCL can appear anaplastic with bizarre pleomorphic nuclei in at least a subset

of cells often with multinucleated forms, and abundant cytoplasm (**Fig. 22-10**),[1] or may mimic metastatic carcinoma because of the cellular pleomorphism, cohesive growth, or sinusoidal infiltration. Other rare cytologic variants include spindle cell, signet ring cells, and others. Occasional cases of DLBCL, NOS and LBCL show plasmacytic maturation, with lymphoma cells admixed with variable numbers of neoplastic mature-looking plasma cells (Figs. **22-11** and **22-12**). These cases should continue to express a mature B-cell immunophenotype. If B-cell markers are missing and plasma-cell markers are present, the separate plasmablastic entities should be considered.

Predominantly medium-sized cells with multiple nucleoli (reminiscent of Burkitt lymphoma [BL]—"intermediate" morphology) or fine chromatin with inconspicuous nucleoli (reminiscent of acute lymphoblastic leukemia/lymphoma—"blastoid" morphology) suggest a diagnosis of HGBL, NOS, HGBL-*MYC/BCL2,* or the provisional entity HGBL-*MYC/BCL6* (**Fig. 22-13** and **Table 22-2**) (covered in **Chapter 23**).

In DLBCL, NOS and other LBCL, there can be variable numbers of reactive cells in the background, such as small lymphocytes (mostly T cells), plasma cells, histiocytes, and neutrophils. Cases with a prominent component of reactive T cells, usually with histiocytes, are categorized as T-cell/histiocyte–rich large B-cell lymphoma (THRLBCL) when no more than 10% of cells are the malignant B cells.[20,21] In rare cases, coalescing small clusters of epithelioid histiocytes are present, mimicking lymphoepithelioid T-cell lymphoma (Lennert lymphoma) (**Fig. 22-14**).[28] Occasional cases may present initially with lymph node infarction or extensive

necrosis.[29] Some uncommon or histologically deceptive morphologic variants are listed in **Table 22-3** (**Figs. 22-15–22-17**).[1,30] A summary of the clinical, morphologic, immunophenotypic, and genetic features of DLBCL, NOS is presented in **Box 22-3**.

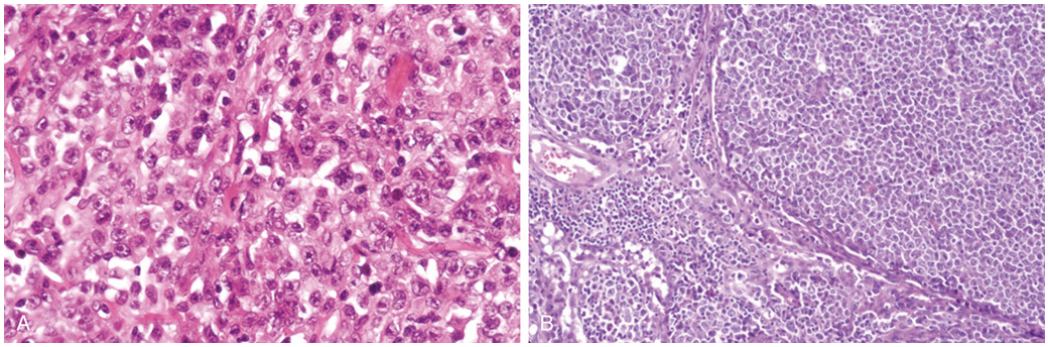

FIGURE 22-3 Nodal diffuse large B-cell lymphoma.**A,** In most cases, the infiltrate comprises noncohesive neoplastic cells growing in a diffuse pattern. **B,** Sometimes the lymphoma cells form nodules or islands that exhibit a sharp interface with the stroma, mimicking carcinoma because of the pseudocohesive appearance or a grade 3 follicular lymphoma because of a pseudonodular appearance. Immunostains for cytokeratins or follicular dendritic cells could be helpful, respectively.

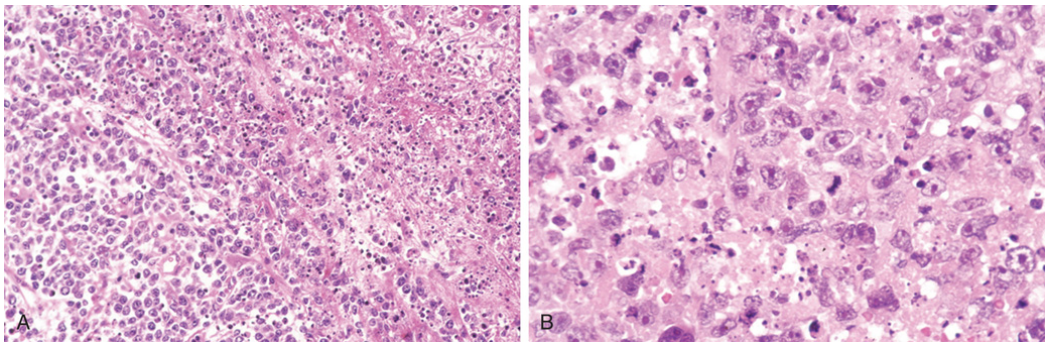

FIGURE 22-4 Diffuse large B-cell lymphoma.**A,** Coagulative necrosis *(upper right portion of the field)* is a fairly common finding and may be extensive. **B,** There may be abundant karyorrhectic debris among the lymphoma cells, mimicking reactive Kikuchi lymphadenitis.

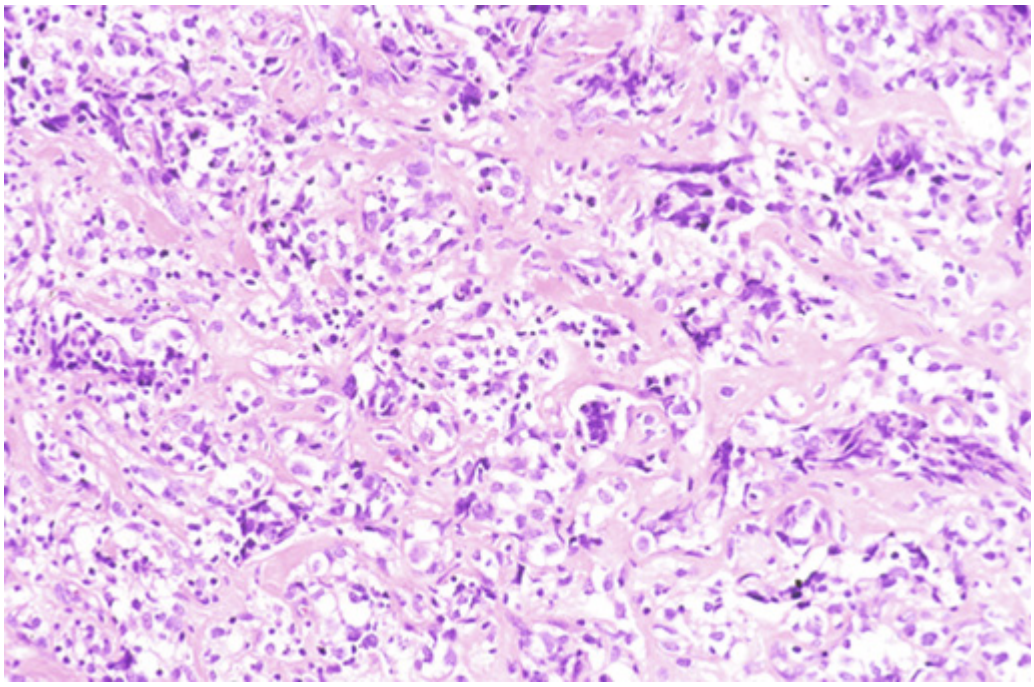

FIGURE 22-5 Diffuse large B-cell lymphoma with sclerosis.Thin sclerotic bands delineate the tumor into irregular packets. Lymphoma cells entrapped in the sclerotic areas often exhibit retracted cytoplasm or crush artifacts.

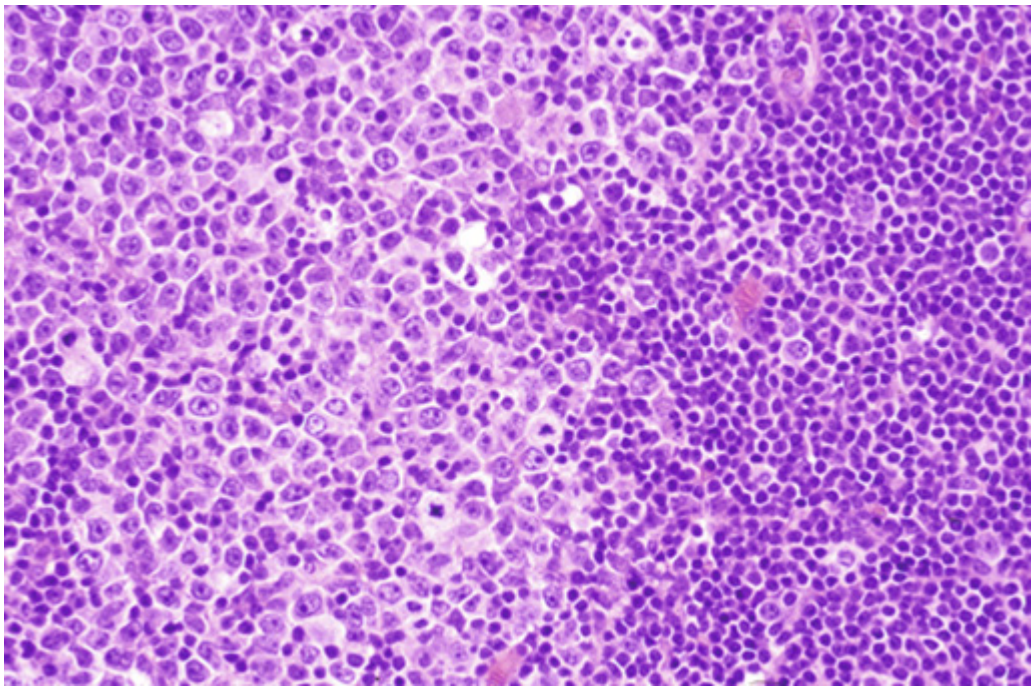

FIGURE 22-6 Diffuse large B-cell lymphoma arising in chronic lymphocytic leukemia (Richter transformation). The *left side* of the field shows diffuse sheets of large lymphoma cells. The *right side* of the field shows the preexisting chronic lymphocytic leukemia, comprising monotonous small lymphocytes; these small cells are confirmed as neoplastic by a CD20-positive, CD5-positive, and CD23-positive immunophenotype *(not shown)*.

Immunophenotype

DLBCL, NOS expresses a mature B-cell immunophenotype including CD45, CD20, CD22, CD19, CD79a, and PAX5 along with surface or cytoplasmic immunoglobulin. Posttherapy, CD20 expression can be lost in tissues from patients previously treated with rituximab (anti-

CD20 chimeric antibody or similar products).[31] Terminal deoxynucleotidyl transferase (TdT) has been reported on DLBCL; however, it is generally weak to variable in intensity and most often focal (with occasional cases showing 60%–70% staining).[32] A study evaluating cases with greater than 10% TdT-positive cells confirmed lack of CD34 expression and the presence of *MYC* rearrangements, including tumors with concurrent *MYC* and *BCL2* rearrangements, indicating that these TdT-positive DLBCL, NOS are sometimes transformational events in DLBCL rather than bona fide B-lymphoblastic lymphomas.[32] Pan–T-cell markers are negative, although CD3 is very rarely expressed (**Fig. 22-18**).[33]

CD10 expression occurs in 20% to 40% of cases.[34-41] CD10 expression on at least 30% of cells is useful in identifying the subset of DLBCL with a germinal-center B-cell–like gene expression profile (GCB-DLBCL).[42,43] The reported positivity rate for the BCL6 protein is highly variable because the criteria for positive staining vary greatly from study to study.[34,39,44-49] Overall, approximately 70% of cases are BCL6 positive when cases with large aggregates of positively stained tumor cells are considered (**Fig. 22-18C**).[49] Some DLBCLs express post–germinal center or plasma cell–associated markers such as CD38, VS38, and IRF4/MUM-1. However, CD138 expression is seen almost exclusively in tumors showing morphologic evidence of plasmacytic differentiation, such as plasmablastic lymphomas (see **Chapter 24**).[39,50]

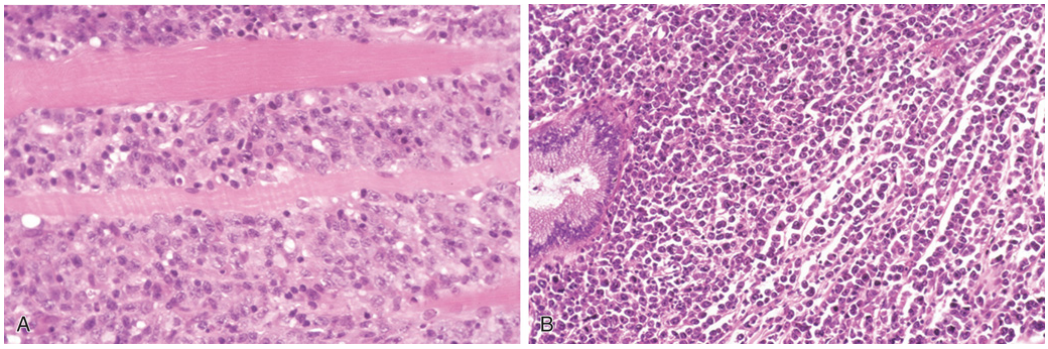

FIGURE 22-7 Extranodal diffuse large B-cell lymphoma.**A,** The interstitial infiltrate splits up and destroys the skeletal muscle fibers. **B,** In the fibrous stroma (uterine cervix in this example), a single-file pattern of infiltration can be seen.

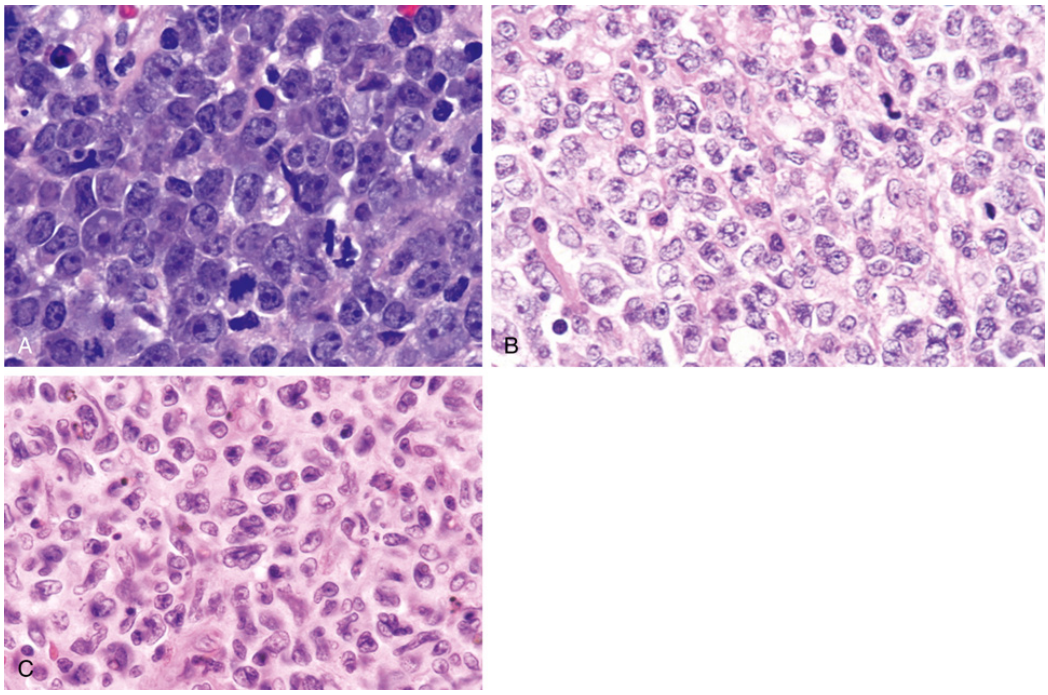

FIGURE 22-8 Diffuse large B-cell lymphoma, cytology.**A,** The centroblasts have round nuclei, vesicular chromatin, multiple small nucleoli adjacent to the nuclear membrane, and a thin rim of cytoplasm. **B,** The large lymphoma cells show angulated or cleaved nuclei and the small nucleoli that are obscured by nuclear folds. **C,** These are large centrocytes, rather than centroblasts, so follicular lymphoma should be considered.

The reported positivity rate for MYC protein expression in DLBCLs varies widely from 12% to 65% (~50% overall),[51-59] attributable to the different cutoff values used (≥40% being the most popular for prognostic purposes; however, other studies have used 70%).[51,60,61] Tumor heterogeneity and whether very weakly stained cells are included in the count also contribute to the variation in cases considered positive.[62] MYC protein expression does not necessarily

correlate with *MYC* rearrangement with a false negative rate of up to 25%[63-65]; thus its possible role as a screening test to predict presence of *MYC* rearrangement by fluorescence in situ hybridization (FISH) may be limited.[53,66,67] Mechanisms of false MYC IHC negativity for *MYC* locus rearrangement include low *MYC* expression and presence of the MYC N11S polymorphism.[65]

About 70% of cases express the BCL2 protein,[39-41,68-70] with a higher frequency observed in nodal than extranodal tumors.[71] The variations in reported BCL2 positivity rate in DLBCL can be explained by the different cutoff values and antibodies used in different series.[72] BCL2 expression in DLBCLs is associated with *BCL2* translocation or copy number alterations but there are discrepancies between *BCL2* translocation and BCL2 expression, which may be related to mutation of the *BCL2* gene at the antibody epitope binding site, type of antibody used, and phosphorylation of the BCL2 protein.[72,73]

CD5 is expressed in approximately 5% to 10% of cases of DLBCL (**Box 22-4**),[44,74-79] and it is unclear whether de novo CD5-positive DLBCL represents a distinct clinicopathologic entity or merely an immunophenotypic variant of DLBCL, lacking relationship with CLL or mantle cell lymphoma (MCL), and associated with adverse prognostic features. The median age of patients with CD5-positive DLBCL, NOS is in the seventh decade. Four different morphologic variants of CD5-positive DLBCL, NOS have been described.[74,79,80] CD5-positive DLBCL, NOS may show aggressive clinical features.[76,81,82]

The activation marker CD30 is expressed in at least some degree in 14% to 25% of cases, which may be important because CD30 is a

potential target for therapy.[83-86] A small proportion of DLBCLs (~2% overall) express cyclin D1 protein, often in only a proportion of tumor cells, with weak to moderate intensity.[87-90] However, in contrast to MCL, cyclin D1-positive DLBCL, NOS do not express CD5 and SOX11 and lack the *CCND1* gene translocation (with rare exceptions).[87-93]

Ki67 staining in DLBCL usually shows a high proliferation index (>30%, but often <80%), and some cases may show an index approaching 100%.[94-97]

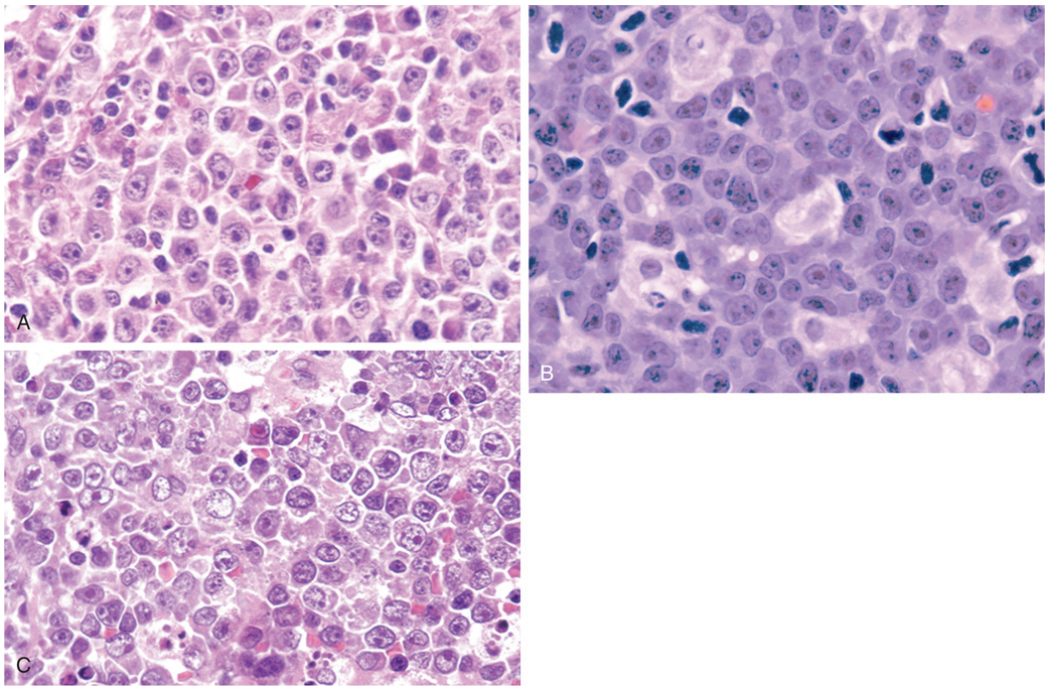

FIGURE 22-9 Diffuse large B-cell lymphoma, immunoblastic subtype.**A** and **B,** Nearly all of the large lymphoma cells show round or oval nuclei, prominent central nucleoli, and a broad rim of amphophilic cytoplasm (immunoblasts). **C,** This case shows immunoblasts mixed with centroblasts; there are also many cells with an indeterminate appearance between the two cell types and, strictly speaking, would not meet criteria for immunoblastic subtype.

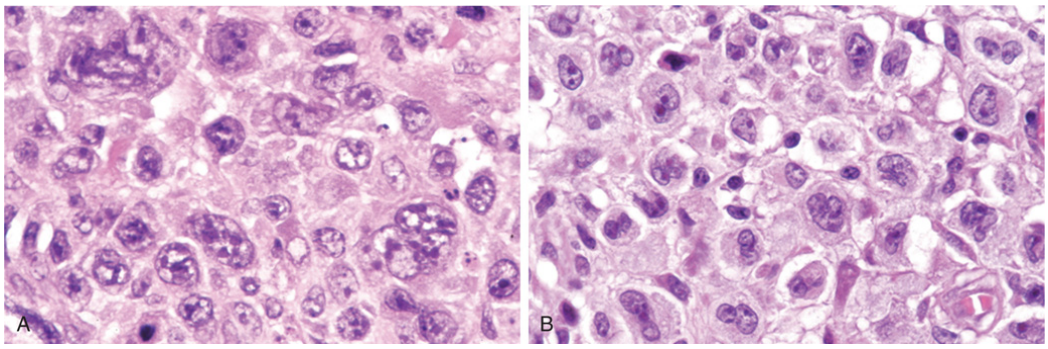

FIGURE 22-10 Diffuse large B-cell lymphoma with anaplastic cytology.**A,** All the cells are much larger than the usual immunoblasts or centroblasts, and some cells are huge and bizarre. **B,** The lymphoma cells are very large, with indented or irregularly folded nuclei and abundant cytoplasm, resembling those seen in anaplastic large cell lymphoma.

Genetics

DLBCLs have clonally rearranged immunoglobulin heavy chain and light chain genes (IGH, IGK, and IGL) and germline T-cell receptor (TR) genes. The immunoglobulin heavy chain variable region gene (IGHV) is usually hypermutated, with some cases showing ongoing somatic mutations.[98,99] In addition to the mechanisms of mutations observed in other tumors, mutations arise in DLBCL and LBCLs through aberrant activity of the mechanisms by which IG loci undergo V(D)J recombination and somatic hypermutation.[100] Errors in V(D)J recombination and class switch recombination are the origin of many of the observed recurrent chromosomal rearrangements. In aggregate, these genetic aberrations give rise to

inappropriate cell proliferation and survival, blocks to terminal B-cell differentiation, and immune evasion, among others.

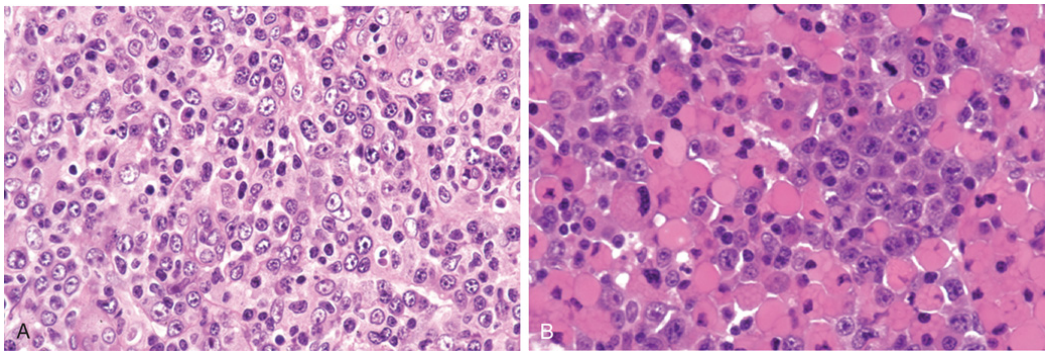

FIGURE 22-11 Diffuse large B-cell lymphoma with plasma-cell differentiation.**A,** In this example, the large lymphoma cells show a gradual morphologic transition to plasmablasts and atypical plasma cells. This appearance is similar to that seen in the polymorphic type of posttransplant lymphoproliferative disorder. **B,** In this example, the large lymphoma cells show an abrupt transition to plasma cells, which are engorged with brightly eosinophilic globules of immunoglobulin, giving a signet ring–style appearance.

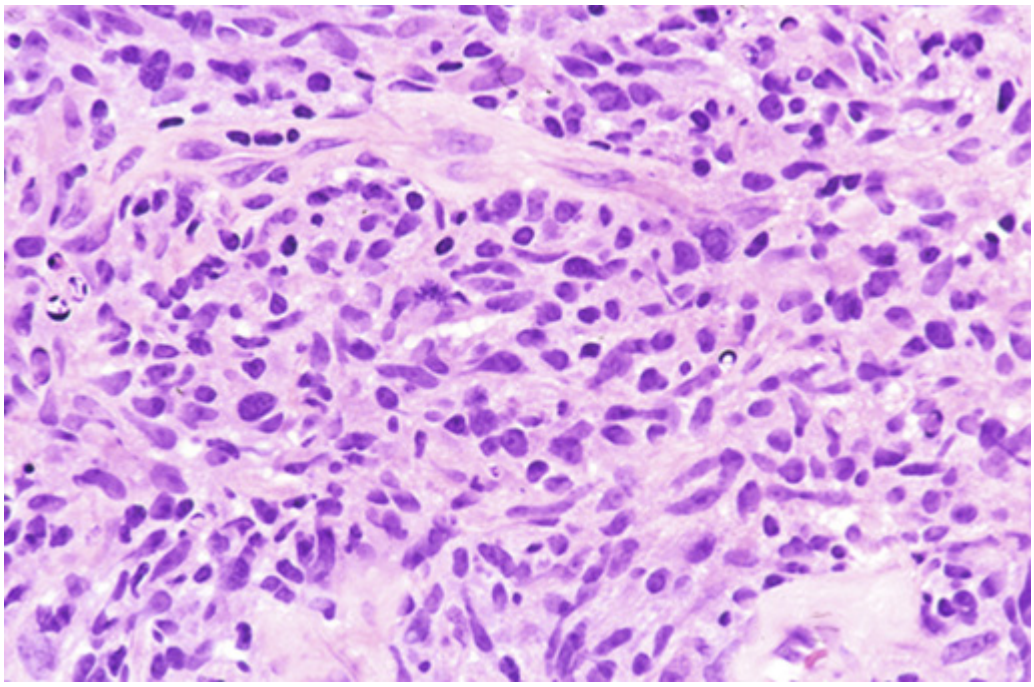

FIGURE 22-12 Diffuse large B-cell lymphoma with spindly lymphoma cells.Nucleoli are usually not obvious unless the cells are examined under high magnification.

The pathogenesis of DLBCL, NOS is complex and appears to involve at least two different pathways: a transformation pathway and a de novo pathway. The genetics-based subtypes of DLBCL, NOS share core mutations with indolent lymphomas, including FL, nodular lymphocyte predominant B-cell lymphoma (NLPBL), MZL, CLL/SLL, and LPL.[101-104]

Recurrent genomic rearrangements are commonly observed in tumors of DLBCL morphology, including *BCL2, BCL6,* and *MYC*. The partners in these rearrangements are typically genes constitutively active in the germinal center, with the resulting promoter or enhancer substitution leading to aberrant expression of these genes. Approximately 20% of tumors harbor t(14;18)(q32;q21) *IGH*::*BCL2*

translocation—a hallmark of FL.[53,55,105-113] These translocations arise during VDJ recombination of the IGH locus in the bone marrow through aberrant activity of recombination-activating genes (RAGs) and, thus, represent a very early event in lymphomagenesis.[114] In DLBCL, NOS, these rearrangements occur almost exclusively in the GCB subtype.[115,116]

BCL6 (3q27) rearrangement occurs in about 30% of DLBCL.[55,107-109,113] The translocation partner can be the IG loci, most commonly in the form of t(3;14)(q27;q32) *BCL6*::*IGH*, or other genes. Somatic mutations of *BCL6,* when coding and noncoding regions are considered, is a common event in DLBCL (73% of cases) and is unrelated to the presence or absence of *BCL6* rearrangement.[117,118] Persistent expression of the BCL6 protein as a result of *BCL6* translocation or mutation inhibits differentiation and apoptosis, resulting in cellular proliferation.[119]

Rearrangement of the *MYC* locus is observed in about 12% of tumors with DLBCL morphology, being more common in HIV-infected patients, pediatric patients, and extranodal lymphomas.[53,55,58,60,65,106-109,113,120-129] In tumors with DLBCL morphology, about 40% to 60% of cases with *MYC* rearrangement represent double-hit or triple-hit lymphoma with coexisting *BCL2* or *BCL6* rearrangement, and such cases are reclassified as HGBL with *MYC* and *BCL2* and/or *BCL6* rearrangements in the 2016 WHO classification (see further discussion of *MYC* rearranged tumor classification updates in **Chapter 23** and **Table 22-1**).[53,55,60,106,107,109,113,123,124] In contrast to BL, *MYC* rearrangements in other aggressive B-cell lymphomas commonly occur as part of a landscape of complex genomic alterations; while

the partner gene, similarly, can be an IG locus, occurring during class switch recombination, approximately half of the rearrangements in HGBL with *MYC* and *BCL2* rearrangements (HGBL-*MYC/BCL2*) are with non-IG genes.[129,130] Within DLBCL, NOS, *MYC* rearrangement (sole by definition) occurs in 2% to 4% of tumors and IG partnership is more common than in HGBL-*MYC/BCL2*.[65,131,132] Other than translocation, increased copy number of *MYC* has been reported in 7% to 38% of cases.[55,125,133,134] Copy number alterations are not considered in the definition of HGBL-*MYC/BCL2* (or HGBL with *MYC* and *BCL6* rearrangements) and *MYC* copy number changes are not consistently associated with increased *MYC* mRNA expression.[135]

Mutation of *TP53* and immunoreactivity for TP53 protein occur in 22% and 40% of DLBCLs, respectively.[105,136] TP53 IHC positivity correlates with the presence of *TP53* missense mutations with sensitivity of 70% to 80%; however, the specificity is lower with a broad range being reported.[137,138] The role of *TP53* in the genesis of DLBCL is unknown, but it may be associated with histologic transformation from an underlying low-grade lymphoma in some cases.[139,140]

A variety of genetic mechanisms contribute to immune evasion in DLBCL. Reduced or absent expression of major histocompatibility complex (MHC) molecules is facilitated through deletion or mutation of *B2M,*[141] deletion of the MHC genes, translocations and mutation of *CIITA,*[142] and mutations that block differentiation in B-cell stages characterized by low MHC expression.[143-145] Mutations in *CD58* allow tumors cells that have lost MHC class I to escape elimination by natural killer (NK) cells.[141] Increased expression of PD-L1 and

PD-L2 is observed with copy number gains,[146] rearrangements[147] and disruption of the 3′UTR of *CD274*.[148]

The availability of next-generation sequencing technology in recent studies has helped unravel the genetic landscape of DLBCL.[101,102,104,149-152] The coding genome contains on average 50 gene alterations per case,[149,150] with an estimated median of 17 genetic driver alterations.[101] These studies have resulted in an evolving definition of genetics-based subtypes within DLBCL, NOS (see **Fig. 22-19**).

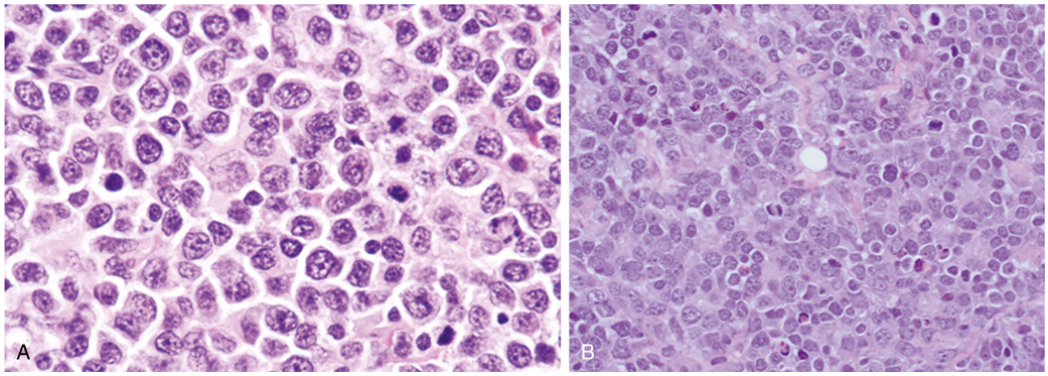

FIGURE 22-13 Intermediate and blastoid cytology.**A,** In this case, medium-sized lymphoma cells with finely clumped chromatin, two to five nucleoli, and minimal cytoplasm are identified showing an intermediate cytology between diffuse large B-cell lymphoma, not otherwise specified (DLBCL, NOS) and Burkitt lymphoma. Because this case did not fulfill the current diagnostic criteria for Burkitt lymphoma, it best fit into the high-grade B-cell lymphoma (HGBL), NOS diagnostic category (see **Chapter 24**). **B,** Another HGBL, NOS shows blastoid cytology with fine chromatin, inconspicuous nucleoli, and minimal cytoplasm. Genetically, there was a *BCL2* rearrangement with *MYC* amplification.

Table 22-2

Molecular Subtypes: Germinal-Center B-Cell–Like and Activated B-Cell–Like Subtypes

Using DNA microarrays to study gene-expression profiles, two groups of DLBCLs corresponding to different stages of B-cell differentiation (cell-of-origin [COO]) can be identified.[153] One group expresses genes characteristic of germinal center B cells (germinal center B-cell–like [GCB] subtype), and the other expresses genes normally induced during in vitro activation of peripheral blood B cells—the activated B-cell–like (ABC) type. The Bayesian model used to assign tumors to the binary ABC and GCB subtypes result in 10% to 20% of tumors being unable to be assigned to either group with sufficient confidence ("unclassified").[154] The GCB, ABC, and unclassifiable groups account for approximately 50% to 60%, 30% to 40%, and 10% to 20% of all DLBCLs, respectively.[115,155] The proportion of ABC subtype is higher in Asian countries, representing 60% of tumors,[156] although this may be because of the higher incidence of DLBCL EBV positive in these countries. The proportion of ABC may increase with patient age.[157]

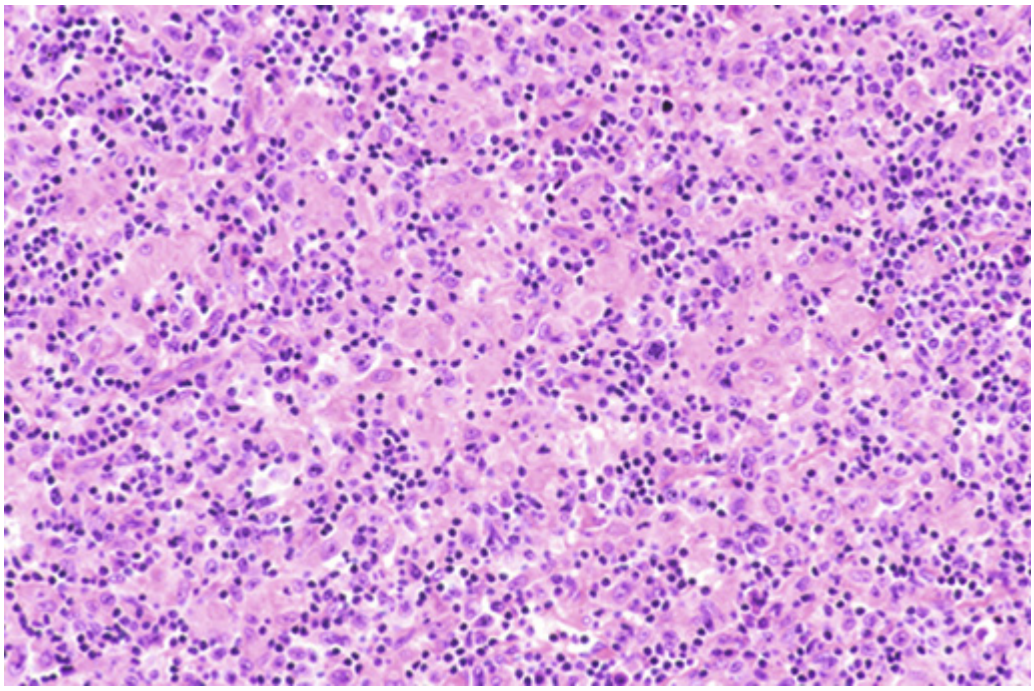

FIGURE 22-14 Diffuse large B-cell lymphoma with many interspersed small clusters of epithelioid histiocytes, reminiscent of Lennert (lymphoepithelioid) lymphoma, a morphological variant of PTCL, NOS.

Because of issues of tissue requirement (fresh or frozen tissue), complexity, and low reproducibility of gene expression profiling using the microarray platform, various molecular methods adaptable to formalin-fixed paraffin-embedded tissues have been developed, analyzing a limited panel of genes based on data from gene expression studies to distinguish the GCB and ABC subtypes.[158-163] The most promising method appears to be the Lymph2Cx assay of 20 genes using the NanoString platform, which is robust and shows excellent interlaboratory agreement.[164-166] Though these methods have not entered routine clinical practice at this time, they have been

applied in prospective clinical trials[167,168] and retrospectively to completed trials.[169-171]

Various immunophenotyping algorithms have also been developed to determine the COO for DLBCLs: GCB subtype versus ABC or non-GCB subtype (**Fig. 22-20**).[43,172-174] However, the correlation with gene expression profiling results is imperfect, with concordance rate of 75% to 90%.[163,165,173] There is also questionable interalgorithm concordance.[175-177] Because the unclassifiable group cannot be recognized by immunophenotyping, such cases will be forced into either the GCB or ABC/non-GCB group. At least in some studies, DLBCLs classified by immunophenotypic algorithms have failed to show prognostic differences between GCB and non-GCB subtypes.[163,175]

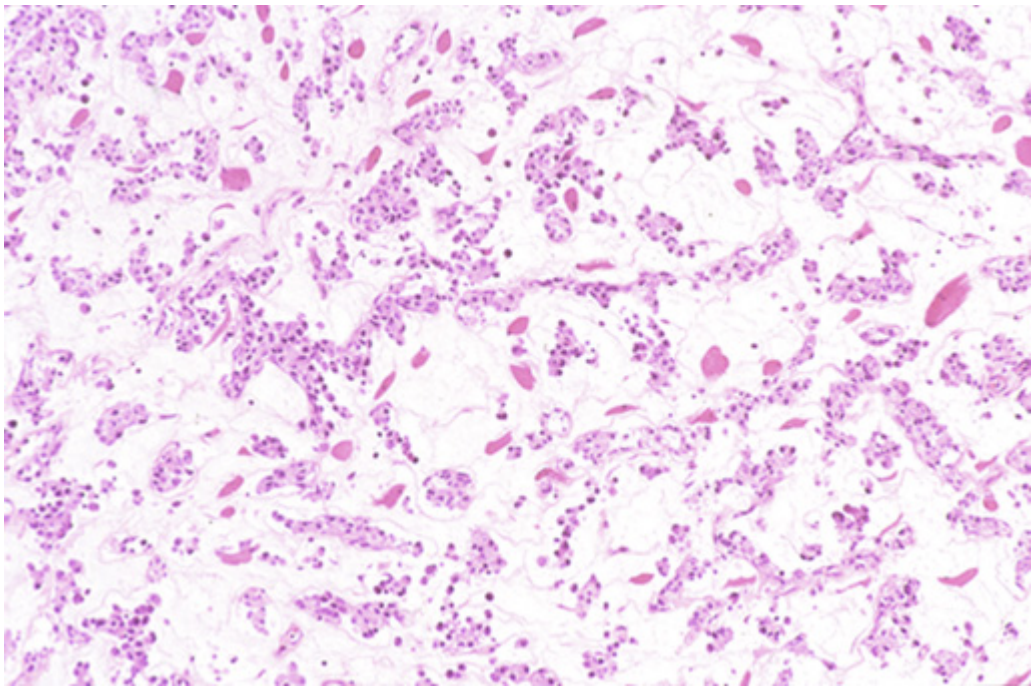

FIGURE 22-15 Diffuse large B-cell lymphoma with abundant myxoid stroma, mimicking extraskeletal myxoid chondrosarcoma.

Table 22-3

Rare Morphologic Variants of Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

Morphologic Variant	Main Pathologic Features	Tumors With Which It Might Be Confused
Myxoid stroma[519,520]	Sheets, cords, or single lymphoma cells suspended in abundant myxoid stroma	Various types of myxoid sarcomas, such as extraskeletal myxoid chondrosarcoma, myxofibrosarcoma
Spindle-cell morphology[521,522]	Lymphoma cells have a spindly appearance caused by spontaneous cellular spindling or molding by collagen; predilection for skin	Various types of spindle-cell sarcomas, spindle-cell carcinoma, desmoplastic melanoma

Morphologic Variant	Main Pathologic Features	Tumors With Which It Might Be Confused
Signet ring–cell morphology[523,524]	Lymphoma cells have cytoplasmic vacuoles, which may be caused by immunoglobulin accumulation or aberrant membrane recycling	Signet ring–cell carcinoma, liposarcoma
Fibrillary matrix or rosette formation[525,526]	Lymphoma cells associated with a prominent fibrillary matrix or rosette formation; because the fibrillary material is formed by interdigitating cytoplasmic processes (hence rich in cell	Neural tumors, such as neuroblastoma, primitive neuroectodermal tumor

Morphologic Variant	Main Pathologic Features	Tumors With Which It Might Be Confused
	membrane materials), it typically shows strong staining for leukocyte markers	
Abundant crystal-storing histiocytes[527]	Lymphoma cells intermixed with histiocytes having ingested crystallized immunoglobulin	Rhabdomyoma
Marked tissue eosinophilia[528]	Lymphoma cells intermixed with numerous eosinophils	Hodgkin lymphoma, peripheral T-cell lymphoma
Microvillous DLBCL[529,530]	Presence of numerous microvillous projections on ultrastructural examination; may show prominent	Anaplastic large cell lymphoma ($CD20^{-}$, $CD3^{+/-}$, $CD30^{+}$, $EMA^{+/-}$, $ALK^{+/-}$, $CD56^{-/+}$); IVLBCL

Morphologic Variant	Main Pathologic Features	Tumors With Which It Might Be Confused
	sinusoidal growth pattern (see **Box 22-2**); $CD20^+$, $CD30^-$, EMA^-, $CD56^{+/-}$	
Sinusoidal $CD30^+$ DLBCL[30]	Sinusoidal growth pattern (see **Box 22-2**); $CD20^+$, $CD30^+$, $EMA^{-/+}$, ALK^-	Anaplastic large cell lymphoma ($CD20^-$, $CD3^{+/-}$, $EMA^{+/-}$, $ALK^{+/-}$); microvillous DLBCL ($CD30^-$); ALK^+ DLBCL ($CD30^-$, ALK^+); IVLBCL; metastatic carcinoma (cytokeratin +); metastatic melanoma ($S100^+$)

ALK, Anaplastic lymphoma kinase; *DLBCL,* diffuse large B-cell lymphoma; *EMA,* epithelial membrane antigen.

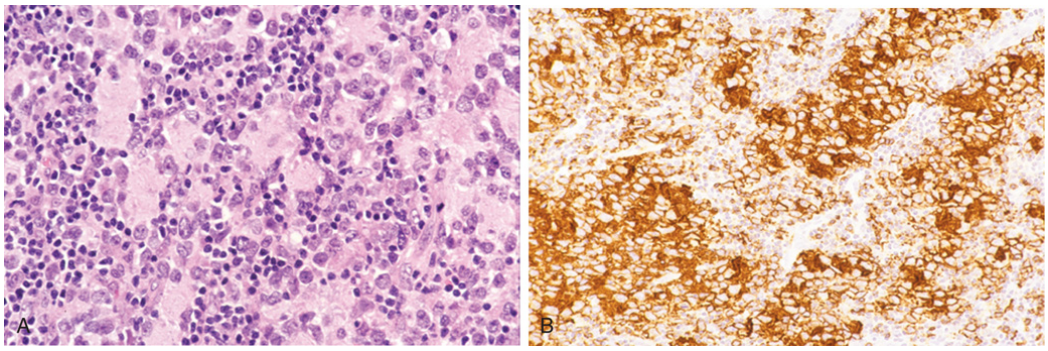

FIGURE 22-16 Diffuse large B-cell lymphoma with fibrillary matrix.**A,** The large lymphoma cells are associated with abundant eosinophilic fibrillary matrix. **B,** The matrix is actually formed by cell membrane materials from the lymphoma cells, as attested to by positive CD20 immunostaining.

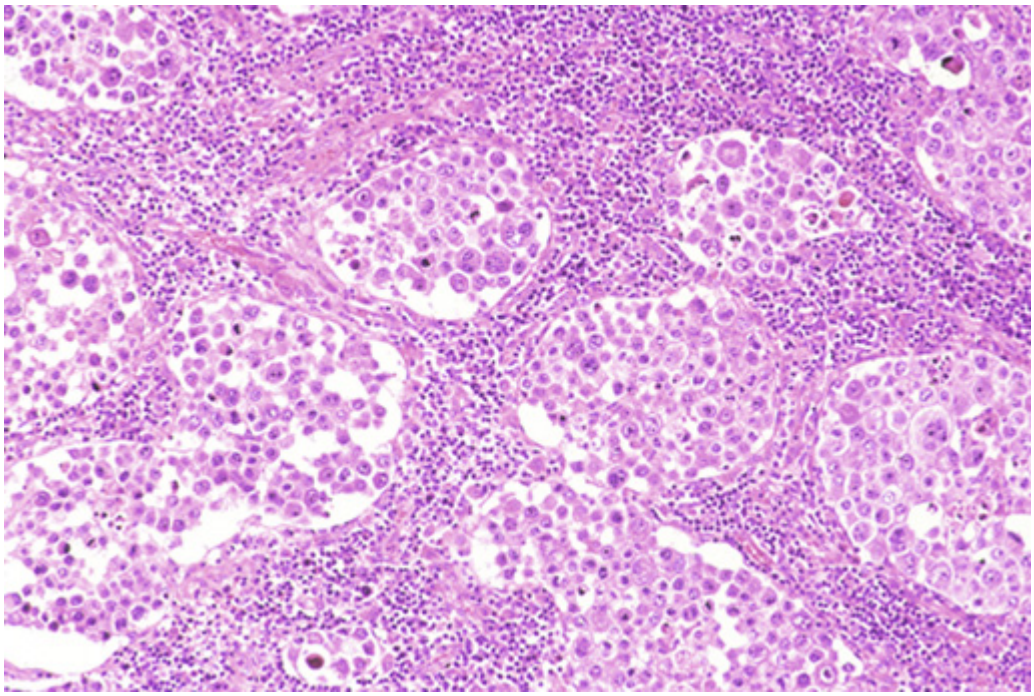

FIGURE 22-17 Sinusoidal CD30-positive diffuse large B-cell lymphoma.The lymphoma cells are confined within the distended sinuses of the lymph node. Care should be taken to exclude an intravascular large B-cell lymphoma.

The COO subtypes of DLBCL, NOS were first recognized in the WHO revised 4th ed. (2016) on the weight of differences in prognosis and molecular features[178] and are retained in the ICC[21] and WHO HAEM5.[20] In comparison with GCB-DLBCL, patients with ABC-DLBCL typically present with higher Ann Arbor stage and International Prognostic Index (IPI) category.[155] Progression-free survival (PFS) at 2 years for ABC-DLBCL has been reported to be 50% to 70% compared with 75% to 85% in GCB-DLBCL in population-based registry[155] and clinical trials,[167,168,179-181] after R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone). Patients with ABC-DLBCL have a higher risk of relapse

within the CNS (9% versus 2% in GCB-DLBCL); however, this was not significant in multivariate analysis when CNS-IPI and MYC/BCL2 dual expression was included.[182] ABC-DLBCLs make up a higher proportion of tumor involving specific extranodal sites, including testicular, breast, and adrenal gland.[183]

The molecular pathogenesis of the ABC and GCB subtypes are distinct and are potentially therapeutically targetable. ABC-DLBCL is characterized by genetic alterations leading to chronic active B-cell receptor (BcR) signaling combined with blockade of differentiation to the plasmablastic stage of differentiation.[150,184] Frequent mutations are observed in the pathway from the BcR to NF-κB, including *CD79B, CARD11,*[185] and *BCL10* and the negative regulator of this pathway, *TNFAIP3*.[186] In addition, frequent mutations are seen in *MYD88* (primarily L265P),[187] which is downstream of toll-like receptors. MYD88 and CD79B have been shown to interact to form a complex, leading to NF-κB signaling.[188] Rearrangements of *BCL6* and mutations and deletions of *PRDM1* are key events resulting in differentiation blockade.[189] Rearrangements of *BCL2* are rare in ABC-DLBCL,[115] while copy number gains are common[116] and result in similar elevation in *BCL2* mRNA.[135] *MYC* rearrangements are also uncommon (2%–4% of tumors)[65] with a predominance of IG loci partners with the breakpoints within the IGH locus consistent with these occurring during class switch recombination.[131]

The genetic landscape of GCB-DLBCL is characterized by mutations affecting the PI3K/Akt/mTOR pathway, chromatin modifiers providing differentiation blockade, and *BCL2* rearrangements. Mutations are observed in *GNA13, S1PR2,* and *FOXO1* along with the negative regulator of the PI3K/Akt/mTOR

pathway, *PTEN*. Frequent mutations are seen in *EZH2, CREBBP* and, less commonly, *EP300,* with functional studies showing their effect on chromatin. *BCL2* rearrangements are detected in 30% to 40% of GCB-DLBCL, when DLBCL/HGBL-*MYC/BCL2* are excluded, while *MYC* rearrangements are rare (2%–4%).[65]

The efficacy of targeting COO specific biology has been tested in a number of large clinical trials, with novel agents added to R-CHOP in order to improve the outcomes of the ABC subtype. Initial reports from these trials have not shown improved outcomes,[167,168,181] with the dominant interpretation being that the binary COO classification of DLBCL, NOS is not sufficiently granular to support precision medicine in this lymphoma. However, recent follow-up of REMoDL-B (testing the efficacy of the addition of a proteosome inhibitor) demonstrates significant improvement in patient PFS and overall survival (OS),[190] while a planned subgroup analysis of PHOENIX (testing the efficacy of the addition of a BTK inhibitor) shows improved outcomes in patients under age 60.[181]

Box 22-3 Major Diagnostic Features of Diffuse Large B-Cell Lymphoma

ABC, Activated B cell; *DLBCL,* diffuse large B-cell lymphoma; *EBV,* Epstein-Barr virus; *GCB,* germinal-center B cells; *NOS,* not otherwise specified.

Clinical Features

- Median age: 64 years
- Slight male predominance

- Presents with rapidly growing nodal (70%) or extranodal (30%) tumor
- B symptoms in one third of cases
- Stage distribution: I, 25%; II, 29%; III, 13%; IV, 33%
- Potentially curable even when widely disseminated; when treated by standard immunochemotherapy, ~70% achieve long-term remission

Morphology

- Diffuse proliferation of large-to-medium-sized lymphoid cells, which can be indistinguishable from normal centroblasts or immunoblasts or can exhibit overt atypia such as irregular nuclear foldings, coarse chromatin, giant size, or bizarre nuclei
- May be associated with an underlying low-grade lymphoma
- Optional cytologic subclassification into centroblastic, immunoblastic, and anaplastic subtypes
- Uncommonly, can show a variety of deceptive growth patterns (e.g., myxoid change, fibrillary matrix, spindle cells); see **Table 22-1**

Immunophenotype

- Positive for pan–B-cell markers (e.g., CD20, CD22, CD79a, PAX5)
- Positive for surface or cytoplasmic immunoglobulin
- BCL6 positive in ~80%
- CD10 positive in ~40%

- CD5 positive in ~5% to 10%
- CD30 positive in ~15%
- CD43 positive in ~25%
- BCL2 positive in ~60%
- Ki67 index: >20% (mean, 55%)
- MYC positive in ~50%

Molecular Features

- Clonally rearranged immunoglobulin genes
- *BCL2* rearranged in ~20%
- *BCL6* rearranged in ~30%
- *BCL6* mutated in ~70%
- *MYC* rearranged in ~12%
- Usually EBV negative, except in the setting of immunodeficiency and the uncommon cases of EBV-positive DLBCL, NOS

Molecular Variants (Cell of Origin)

- GCB subtype: Expresses genes characteristic of GCBs, and accounts for ~50% to 60% of all DLBCLs. More favorable prognosis than ABC type. Common genetic changes: *BCL2* translocation, *REL* amplification, *EZH2* mutation, mutations of genes in the Gα13 pathway.
- ABC subtype: Expresses genes highly expressed during in vitro activation of peripheral blood B cells, and accounts for ~30% to 40% of all DLBCLs. Common genetic changes: Chronic

activation of B-cell receptor pathway, NF-κB pathway activation through mutations in regulator genes of the NF-κB pathway and *MYD88* mutation.

- Unclassified: Unable to be assigned to ABC or GCB subtype with sufficient confidence based on patterns of gene expression.

Genetic Subtypes

Genetics-based classification schema have emerged from three independent studies,[101,102,104] converging on five to seven subtypes based on patterns of co-occurrence of genetic aberrations, encompassing single nucleotide variants (SNVs)/indels, copy number alterations, and structural variants (*BCL2* and *BCL6* rearrangements). The subtypes are prognostic in R-CHOP treated cohorts and the inferred biology underlying the individual subtypes predict response to currently available targeted agents, providing a framework for precision medicine trials and future drug development. A feature across the studies is that most of the defined subtypes share core mutations with indolent B-cell lymphomas. While this may suggest that apparently de novo DLBCLs arise from clinically occult indolent lymphomas, an alternative is that the evolutionary paths to DLBCL and indolent lymphomas share early key genetic driver events. The latter is supported by the study of late relapse of DLBCL, where the diagnostic and relapse tumors demonstrate branched evolution consistent with a common precursor cell.[191] This is further supported by studies of "transformation" of indolent lymphoma to DLBCL.[192]

At this time, the one publicly available approach to assign tumors to genetics-based subtype is a probabilistic classification tool—the LymphGen algorithm.[103] This tool assigns tumors into seven subtypes. While the schema of the three groups have not been formally harmonized, the described subtypes have significant biological similarity (**Fig. 22-21**). In the explanatory section, the LymphGen labels will be used, unless otherwise stated, with the labels from Chapuy et al.[101] and Lacy et al.[104] in brackets after.

The EZB (Cluster C3/BCL2) subtype is characterized by *BCL2* rearrangements and mutations in *EZH2* along with other chromatin modifying genes *(CREBBP)*, *TNFRSF14* loss of function, and *PTEN* inactivation. These tumors are typically GCB-DLBCL. This subtype shares a number of core mutations with FL. EZB is further subdivided into EZB-MYC positive and EZB-MYC negative based on presence or absence of the DHITsig gene expression signature (see prognostic molecular biology features). EZB-MYC negative is associated with good prognosis, while EZB-MYC positive is associated with poor prognosis, emphasizing an ongoing need for gene expression profiling.

The C4 cluster described by Chapuy et al. comprises tumors that are predominantly GCB-DLBCL and have favorable prognosis. It is possible that this cluster is composed of two subgroups. The first is ST2 (TET2/SGK1) with *SGK1* and *TET2* as the hallmark mutations. These tumors share core mutations with NLPBL. The second, labeled SOCS1/SGK1, was described by Lacy et al. and is not represented in LymphGen. Primary mediastinal large B-cell lymphomas (PMBL) mostly fell into the SOCS1/SGK1 group when classified with their schema.[104]

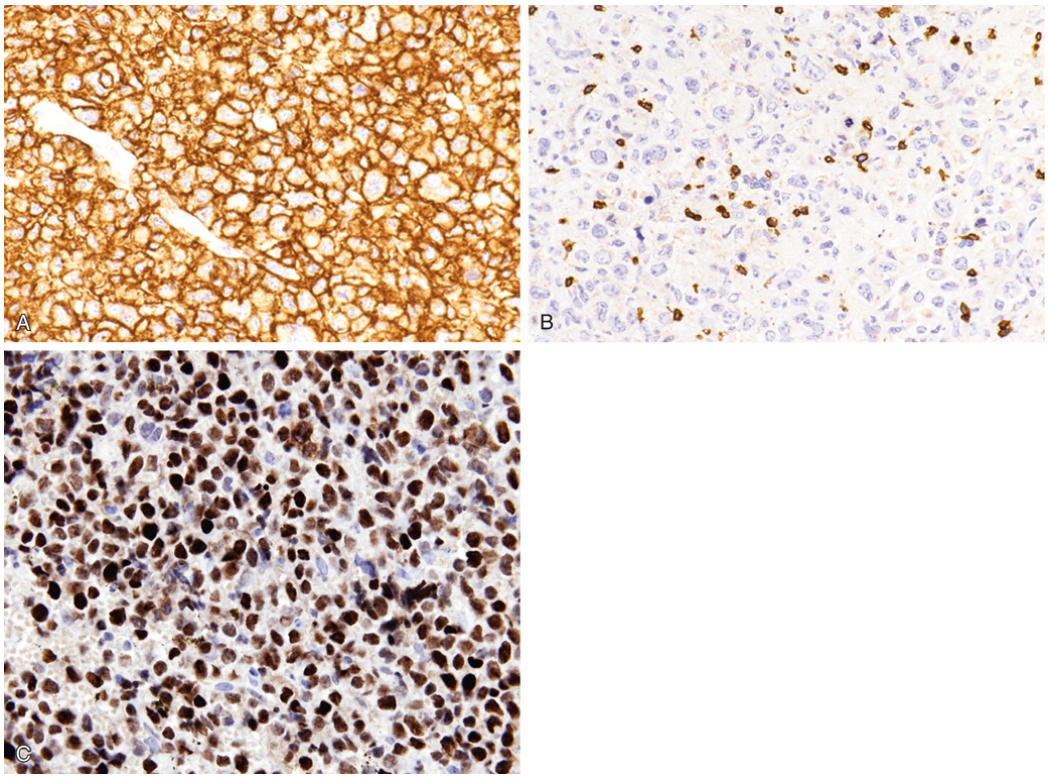

FIGURE 22-18 Immunohistochemistry of diffuse large B-cell lymphoma.**A,** The large tumor cells show strong cell membrane staining for CD20. **B,** The lymphoma cells are not immunoreactive for CD3, but the scattered reactive small T lymphocytes are highlighted by the immunostain. **C,** In this example, most lymphoma cells show nuclear staining for BCL6.

Box 22-4 Major Differential Diagnoses of Diffuse Large B-Cell Lymphoma With CD5 Expression

DLBCL, Diffuse large B-cell lymphoma.

- Mantle cell lymphoma, blastoid or pleomorphic variant
- Paraimmunoblastic variant of chronic lymphocytic leukemia
- DLBCL arising in chronic lymphocytic leukemia (Richter transformation)
- Intravascular large B-cell lymphoma
- Splenic DLBCL
- De novo CD5-positive DLBCL

BN2 (cluster C1/NOTCH2) is characterized by *BCL6* rearrangements and *NOTCH2* mutations. The core mutations are shared with MZL. These tumors make up the majority of DLBCL that are unclassified COO. BN2 is generally associated with favorable outcome.

N1 is a rare subtype characterized by *NOTCH1* mutations, sharing genetic features with CLL/SLL. These tumors are usually ABC-DLBCL and are associated with poor prognosis.

The hallmark mutations in the MCD (cluster C5/MYD88) subtype are $MYD88^{L265P}$ and *CD79B*. By COO, they are ABC-DLBCL and typically have poor prognosis. DLBCL of the CNS and DLBCL of the testis are predominantly MCD subtype as are DLBCL that involve the breast. The core mutations of the MCD subtype are shared with LPL.

The A53 (cluster C2) subtype is defined by *TP53* mutations and complex copy number states. This subtype is associated with poor prognosis and these tumors span the COO groups.

Ongoing refinement is needed to harmonize the three existing schema and to reduce the proportion of tumors (35%) that currently are not assigned with sufficient confidence to any of the seven LymphGen subtypes. For these reasons, the incorporation of the

genetics-based classification into either ICC or WHO HAEM5 was deferred to future classifications. However, the promising results emerging from retrospective application to clinical trials[171] and the intention to design prospective precision medicine trials around these schema[191] highlight the future importance of this classification system.

Postulated Cell of Origin

The postulated COO of DLBCL, NOS is the germinal center or post–germinal center B cell for the GCB and ABC subtypes, respectively.

Clinical Course

Although DLBCL is an aggressive tumor, usually resulting in death within 1 or 2 years if left untreated, it is a potentially curable disease even when widely disseminated.[24] The vast majority of relapses occur in the first 2 years after diagnosis and OS for patients event-free at 24 months are reported to be equivalent to that of the age- and sex-matched general population (see **Fig. 22-22**).[193] R-CHOP was established as the standard of care over 2 decades ago when the addition of the anti-CD20 antibody to CHOP was shown to provide superior outcomes.[194,195] R-CHOP (with or without radiotherapy) results in long-term remission in 60% to 70% of patients.[24] Recently the addition of polatuzumab (an antibody drug conjugate) to R-CHP (without vincristine) has been shown to improve outcomes over R-CHOP.[170] Outcomes of patients that experience relapse or progressive disease have been poor, particularly if the relapse occurs within the first 12 months.[196] Historically, fit, younger patients have been treated with intensive chemotherapy followed by autologous

stem cell transplantation, achieving long-term remission in 20% to 30% of patients.[197] The recent advent of chimeric antigen receptor T-cell (CAR-T) therapy and bispecific antibodies improve the outcomes of patients with relapsed disease, either used in those patients ineligible for transplant (or experiencing disease relapse after transplant) or in those with disease that relapses within 12 months of first-line therapy.[198-201]

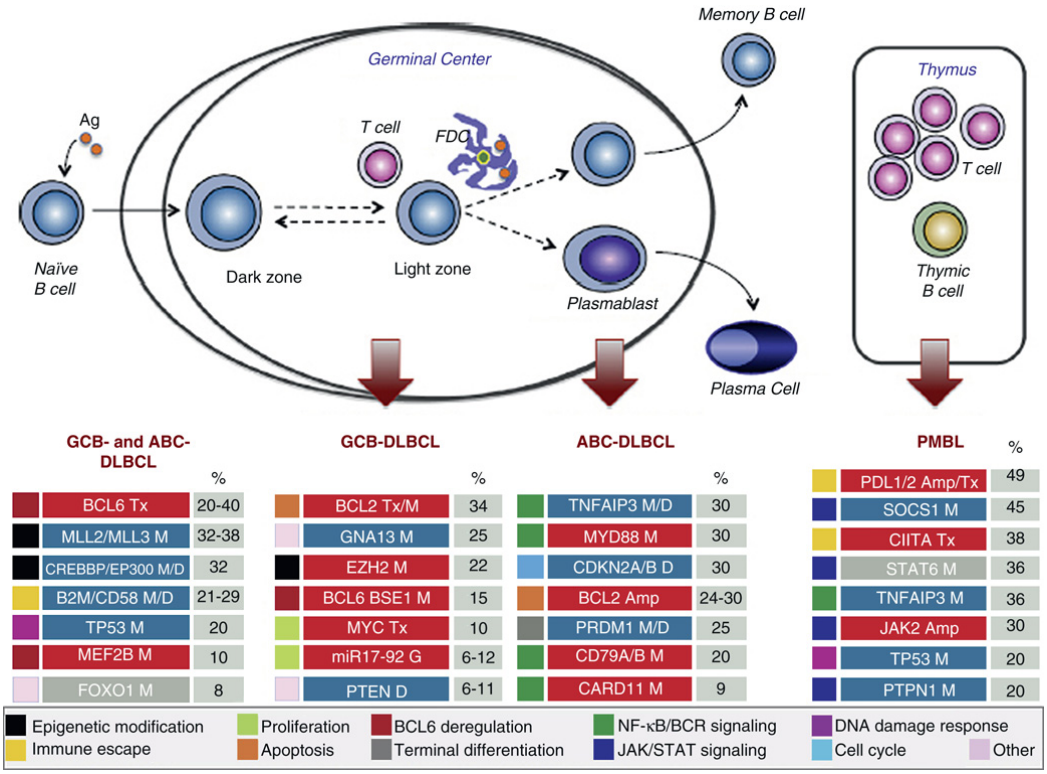

FIGURE 22-19 Germinal-center and diffuse large B-cell lymphoma pathogenesis.Schematics of the germinal-center reaction and its relationship with major molecular subtypes of diffuse large B-cell lymphoma. The most common shared and subtype-specific genetic alterations are shown, with color codes indicating the involved biological pathway. Loss of function *(blue)* and gain of function *(red)* are shown. *ABC,* Activated B cell; *Ag,* antigen; *Amp,* amplification; *D,* deletion; *DLBCL,* diffuse large B-cell lymphoma; *FDC,* follicular dendritic cell; *G,* gain; *GCB,* germinal-center B cell; *M,* mutation; *PMBL,* primary mediastinal large B-cell lymphoma; *Tx,* translocation. From Pasqualucci L, Dalla-Favera

R. The genetic landscape of diffuse large B-cell lymphoma. Semin Hematol. 2015;52:67-76, © Elsevier Inc., Figure 1.

Pediatric patients with DLBCL have better outcome (3-year/5-year event-free survival of ~90%) compared with adult patients, and they used to be treated with aggressive chemotherapy regimens similar to those for patients with Burkitt lymphoma.[202,203] The difference in clinical behavior is at least partly related to the different biological features of DLBCL in children: more commonly of the GCB group (~80%),[204,205] lack of *BCL2* translocation,[203] frequent *MYC* rearrangement (33%, associated with a more complex karyotype),[126] and molecular signature of Burkitt lymphoma in ~30% of cases.[206] The use of strict age cutoff to determine treatment protocol has been challenged because this cannot be defined for the age-related biological characteristics.[207] It has only recently been demonstrated that the addition of rituximab to these regimens improves outcomes in this population.[208]

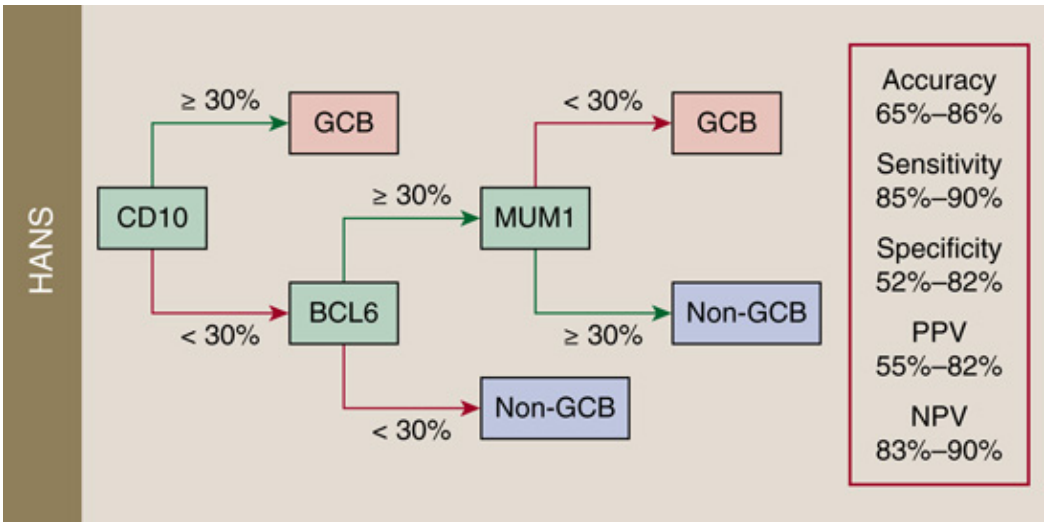

FIGURE 22-20 Subclassification of diffuse large B-cell lymphoma, not otherwise specified into germinal center B-cell–like (GCB) subtype and non-GCB subtype using immunohistochemistry. The "Hans" algorithm is shown with test characteristics using gene expression profiling as the gold standard.

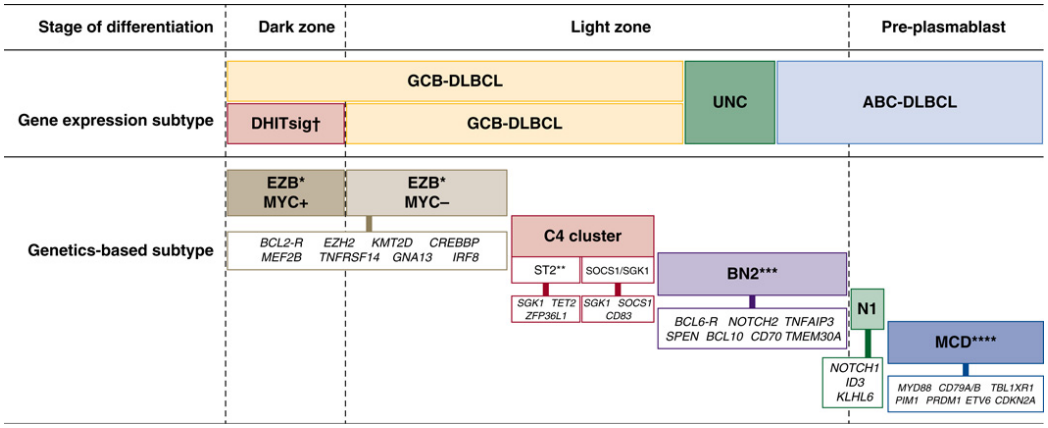

FIGURE 22-21 Schematic showing the relationship between the cell of origin subtypes and the genetics-based subtypes.The stage of B-cell differentiation most similar to the tumor cells, based on gene expression profiling, is shown at the top. The characteristic genetic mutations and rearrangements are shown below each genetics-based subtype. The A53 (cluster C2) is not shown. †DHITsig or MHG (molecular high grade) signature; ⁎aligned with cluster C3 and BCL2; ⁎⁎aligned with TET2/SGK1; ⁎⁎⁎aligned with C1 and NOTCH2; ⁎⁎⁎⁎aligned with C5 and MYD88. *ABC,* Activated B-cell-like subtype; *DHITsig,* double-hit signature; *DLBCL,* diffuse large B-cell lymphoma; *GCB,* germinal center B-cell-like subtype; *UNC,* unclassified.

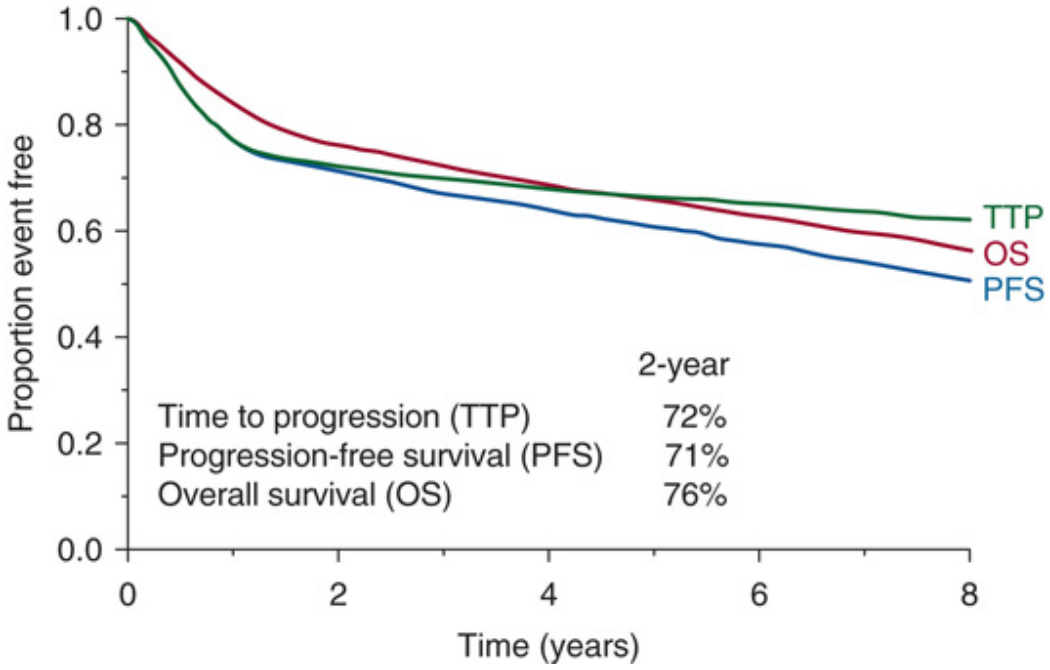

FIGURE 22-22 Outcome curve of patients with diffuse large B-cell lymphoma after treatment with rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP). The data shown are from 3264 patients diagnosed between 2001 and 2022 in British Columbia, Canada. *OS,* Overall survival (events are death from any cause); *TTP,* time to progression (events are progression, relapse, or death from lymphoma or toxicity of lymphoma treatment); *PFS,* progression-free survival (events as per TTP but also including death from any cause).

Prognostic Factors

The adverse prognostic factors in DLBCL are listed in **Box 22-5**.

Prognostic Clinical Features

The IPI, first defined in 1992, remains a reliable predictor of outcome (**Table 22-4**).[209] The revised IPI, based on redistribution of the individual IPI factors, has been reported to provide a better prediction of outcome in patients treated with R-CHOP.[210] Finally, the recently described NCCN-IPI further refines prognostication.[211] A clinical model, the CNS-IPI, has been developed and validated to identify patient groups with different risk of relapse of DLBCL within the CNS.[212] Short interval, particularly 2 weeks or less, between diagnosis and treatment has been associated with poor prognosis.[213] This patient group had significantly higher proportions of recognized poor prognosis factors.

Prognostic Morphology and Bone Marrow Involvement

Some but not all studies have shown a slightly poorer outcome for immunoblastic lymphoma compared with centroblastic lymphoma.[128,214-216] The greatest problem with most of these studies is that reproducibility in the subclassification is not addressed. The plasmablastic variant is associated with poor outcome (see **Chapter 24**).

In DLBCL cases with discordant bone marrow histology (i.e., bone marrow involved by indolent lymphoma instead of DLBCL), survival is better than in cases with concordant bone marrow histology (i.e., involvement by DLBCL). In fact, the survival of the former group is similar to that of patients with negative bone marrow,[26,217] although there is a higher risk for late relapse.[218]

Prognostic Immunohistochemistry

Many studies have shown that immunohistochemistry (IHC) markers, alone or in combination, have prognostic effects in the R-CHOP era. It should be noted that these are not predictive of response to particular therapies at this time and so are not widely used to dictate treatment. COO, as determined by IHC-based algorithms, has been shown to be prognostic in a number of studies,[172-174,219] although this association has been inconsistent and a meta-analysis did not confirm this finding.[220] This may be partly explained by the limitation in reproducibility and accuracy of the IHC-based assays.[165,175]

Dual protein expression of MYC and BCL2 (double-expressor lymphoma) has been established as a strong prognostic biomarker,[51,53,59] with the usual thresholds being ≥40% and ≥50% of malignant cells, respectively. Importantly, dual protein expression does not define a biologically homogeneous group, with ABC-DLBCL (the majority of these tumors) and GCB-DLBCL arriving at this immunophenotype through different mechanisms.[116] This dual expression of MYC and BCL2 protein is prognostic for DLBCL, NOS and is distinctly different from double-hit rearrangements of *MYC* and *BCL2,* which together define a separate disease.

Box 22-5 Poor Prognostic Indicators in Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

ABC, Activated B-cell–like; *IHC,* immunohistochemistry; *IPI,* International Prognostic Index.

Clinical

- High IPI score
- Short time from diagnosis to treatment

Morphologic

- Immunoblastic or plasmablastic morphology

Immunohistochemical

- Lack of germinal-center cell phenotype (Hans algorithm)
- Double expression of MYC and BCL2
- CD5 expression
- High proliferation (Ki67) index (controversial)
- Lack of CD30 expression
- TP53 protein expression
- Lack of HLA-DR expression
- Poor tumor-infiltrating T-cell response, especially CD4-positive or FOXP3-positive T cells
- High numbers of granzyme B-positive or TIA-1-positive tumor-infiltrating T cells

Molecular

- ABC subtype by gene-expression profiling or IHC algorithm
- Double-hit or molecular high-grade gene expression signature
- *TP53* mutation

Table 22-4

De novo CD5-positive DLBCL is associated with a poorer outcome compared with CD5-negative DLBCL,[44,74,80] and is prone to CNS recurrence.[79,80] In the R-CHOP era, CD5 expression remains a significant poor prognostic factor (40%–50% 2-year OS for CD5 positive versus 75%–90% for CD5 negative).[79,221] CD30 expression has been shown to be associated with favorable clinical outcome, especially in GCB subtype and EBV-negative cases.[83,84]

The prognostic significance of the proliferation index as measured by Ki67 immunostaining or other techniques is conflicting. The Southwest Oncology Group and two other groups reported that a high proliferation index (>60%–80%) is associated with poor prognosis.[94,222-225] In contrast, at least two studies have reported the reverse finding.[226,227] The prognostic significance of the proliferative index remains inconsistent in the rituximab era.[54,228,229] Positivity for TP53 by IHC has been associated with poor outcomes, independent of IPI and COO.[137,230]

Signaling the importance of tumor microenvironment, absent MHC class II expression,[144,222,231,232] low tumor-infiltrating T-cell response (especially CD4-positive T cells or FOXP3-positive regulatory T cells),[233-237] and high numbers of granzyme B or TIA-1–positive tumor-infiltrating T cells[238-240] are associated with poor clinical outcome.

Prognostic Molecular Biology Features

COO, assigned using gene expression methods, has been reported in most[155,163,169,241] but not all[179] studies to be prognostic of outcomes after R-CHOP. Recently the COO model has been further refined,

recognizing subgroups within the GCB subtype. Anatomically and functionally, the germinal center can be divided into the dark zone, where proliferation and somatic hypermutation of the IGV regions occur, and the light zone, where the B cells undergo selection through interactions with T_{FH} cells in the presence of follicular dendritic cells. Studies have indicated that GCB-DLBCL can be further divided into tumors with gene-expression patterns reminiscent of the dark or light zone.[242-244] The molecular high-grade (MHG) signature[244] was directly derived from the gene expression signatures that were previously shown to distinguish between Burkitt lymphoma (BL—the prototypical dark zone lymphoma) and DLBCL.[130,245] The double-hit signature (DHITsig) defined as the gene-expression pattern that distinguishes HGBL-*MYC/BCL2* from GCB-DLBCL[243] is a misnomer, as all BLs also express this signature, leading to the pattern being renamed the *dark-zone signature*.[246] These signatures are functionally very similar and 30% to 50% of tumors of DLBCL morphology that express these dark-zone signatures are HGBL-*MYC/BCL2,* while a small proportion that are not assigned to HGBL-*MYC/BCL2* by FISH harbor cryptic rearrangements.[247] GCB-DLBCLs (i.e., not HGBL-*MYC/BCL2*) that express DHITsig/MHG have similarly poor outcomes to HGBL-*MYC/BCL2,* but it is not clear whether these patients benefit from the treatment escalation used by many centers for HGBL-*MYC/BCL2*. Patients with "light-zone" GCB-DLBCL have excellent outcomes, even with advanced stage disease.[243]

Gene-expression studies have identified a number of prognostic biomarkers for DLBCL, NOS, beyond the COO subtypes. The tumor microenvironment, as determined in gene expression, is also

prognostic.[241] These signatures, stromal-1 and stromal-2, have been refined and developed into an assay applicable to formalin-fixed paraffin embedded biopsies—the lymphoma-associated macrophage interaction signature (LAMIS).[248] A number of other studies have identified further prognostic microenvironment signatures.[249-251] Kotlov et al. identified four groups (GC-like, mesenchymal, inflammatory, and depleted) with distinct outcomes. Meanwhile, Steen et al. developed EcoTyper, a bioinformatic tool that deconvolutes bulk RNA-sequencing to infer the abundance of states of the malignant B cells alongside tumor microenvironment composition.[251] They identified 9 main clusters of B cell state and microenvironment compositions, labeled lymphoma ecosystems, that have distinct outcomes.

In the absence of *MYC* rearrangement, most, but not all, series show no prognostic significance of *BCL2* or *BCL6* rearrangement in DLBCL.[53,55,68,106-113,252-255] The presence of *BCL6* gene mutation is suggested to be a favorable prognostic factor.[255,256] High levels of *BCL6* mRNA expression are associated with a favorable prognosis.[255,257] Sole *MYC* rearrangement, in the absence of concurrent *BCL2* or *BCL6* rearrangement, is variably associated with poor outcomes,[129] with the largest series finding no association.[132]

TP53 mutation generally correlates with poor prognosis on multivariate analysis, and the effect may depend on the types of mutations.[258-261] Deletion of *CDKN2A* has also been reported to be associated with poor prognosis.[262] The prognostic significance of clusters of mutations are discussed in the section on the genetics-based subtypes of DLBCL.

Differential Diagnosis

In general, the diagnosis of DLBCL is straightforward and established by clinical history, radiologic and laboratory findings, appropriate histology and cytology, immunohistochemistry revealing a mature B-cell immunophenotype, and demonstration of monoclonality of the immunoglobulin heavy or light chains via expression patterns or genetic analysis (**Table 22-5**). Most important, a benign lymphoid proliferation should be excluded. In addition, the more specific entities in this and other chapters (virally associated LBCL, immunodeficiency associated, etc.) should be excluded as far as possible.

Benign

Reactive B-cell proliferations can be tricky, particularly in small biopsies and in children. In florid reactive immunoblastic proliferations, such as infectious mononucleosis, other viral infections (including cytomegalovirus infection), drug reactions, and postvaccination reactions, the lymph node shows partial effacement of nodal architecture and infiltration by many large lymphoid cells, closely mimicking DLBCL (**Fig. 22-23**).[263] The subtotal effacement of the lymph node in infectious mononucleosis and other viral and reactive cases can be difficult to detect in core needle biopsies in which the nodal architecture cannot be appreciated, warranting caution. In addition, necrosis is common and Reed-Sternberg–like cells are occasionally found, especially around the necrotic foci. In contrast to DLBCL, the large, activated cells in reactive proliferations often show transition and maturation into plasmablasts and plasma cells, and they usually do not show significant nuclear atypia such as irregular or twisted nuclear outlines. By immunophenotyping, the

large cells in infectious mononucleosis consist of a mixture of B cells and T cells, and the B cells are polytypic.[264] Because there is a mixture of B cells at various stages of maturation toward plasma cells, CD20 staining is heterogeneous (with staining lost in late plasmablasts and plasma cells) (**Fig. 22-24**). Many cells are immunoreactive for EBV-LMP1. Correlation with clinical findings and serology can assist in arriving at the correct diagnosis.

Another diagnostic dilemma is that of Kikuchi (histiocytic necrotizing) lymphadenitis. The lymph nodes show subtotal effacement by patchy, karyorrhectic foci commonly associated with many large lymphoid cells, which may initially mimic DLBCL. In contrast to DLBCL, the proliferating cells in Kikuchi lymphadenitis consist of histiocytes (CD68 positive, myeloperoxidase positive), plasmacytoid dendritic cells (CD68 positive, CD123 positive, myeloperoxidase negative), and cytotoxic CD8-positive T cells, with very few CD20-positive B cells. Some of the histiocytes are typically packed with phagocytosed materials, compressing the nuclei into a thin crescent (crescentic histiocytes).[265-267]

Table 22-5

ALK, Anaplastic lymphoma kinase; *DLBCL, NOS,* diffuse large B-cell lymphoma, not otherwise specified; *EBV,* Epstein-Barr virus; *HHV-8,* human herpesvirus 8; *L&H,* lymphocytic and histiocytic; *NK,* natural killer.

B-Cell Lymphomas

Cases of DLBCL, especially those accompanied by many apoptotic bodies and a starry-sky pattern, can be difficult to distinguish from

BL. Examination of such cases should demonstrate one of the DLBCL cytologies (most commonly centroblastic features) that are distinct from the neoplastic cells in BL, which are usually more monotonous and often exhibit molding of the nuclei and cytoplasmic borders. Immunophenotyping can also be helpful because BL will show expression of germinal center markers (CD10, BCL6) and lack, or have only weak, BCL2 expression. In addition, Burkitt lymphoma should show an extremely high proliferation (Ki67) index, approaching 100%; this is much higher than DLBCLs as an overall group, although occasional examples of DLBCL can show proliferation in this range. *MYC* rearrangement, a characteristic of Burkitt lymphoma, is uncommon in DLBCLs (~10%) and usually occurs as part of a complex genetic aberration.[130] Importantly, DLBCLs with sole *MYC* rearrangement do not typically show the gene expression profile of Burkitt lymphoma; instead, they are similar to DLBCL without *MYC* rearrangement.[130,245] The categories of HGBL, NOS or HGBL-*MYC/BCL2* should be considered and excluded (see **Chapter 24**).[20,21]

The pleomorphic and blastoid variants of MCL, which are comprised of large pleomorphic cells with irregularly folded nuclei or moderately sized cells with fine chromatin, respectively, can be difficult to distinguish from DLBCL, NOS (**Fig. 22-25**).[268-272] However, in these variants, there are often foci with features of classic MCL, including naked germinal centers lacking organized mantle zones or foci with the more usual mantle cell cytology. Evaluation for expression of cyclin D1, SOX11, and CD5 along with FISH for the *CCND1* gene translocation can be helpful to distinguish the two entities.[87-93]

The paraimmunoblastic type of CLL/SLL is an aggressive variant characterized by diffuse infiltration of paraimmunoblasts—the cell type commonly found in proliferation centers.[273,274] Paraimmunoblasts, which are medium-sized cells, are slightly smaller than the lymphoma cells seen in DLBCL. They have vesicular nuclei, single central nucleoli, and a moderate amount of weakly eosinophilic rather than amphophilic or basophilic cytoplasm (**Fig. 22-26**). Furthermore, intermixed prolymphocytes and small lymphocytes are often seen, the lymph node capsule is often preserved, and CD5 is positive.[273]

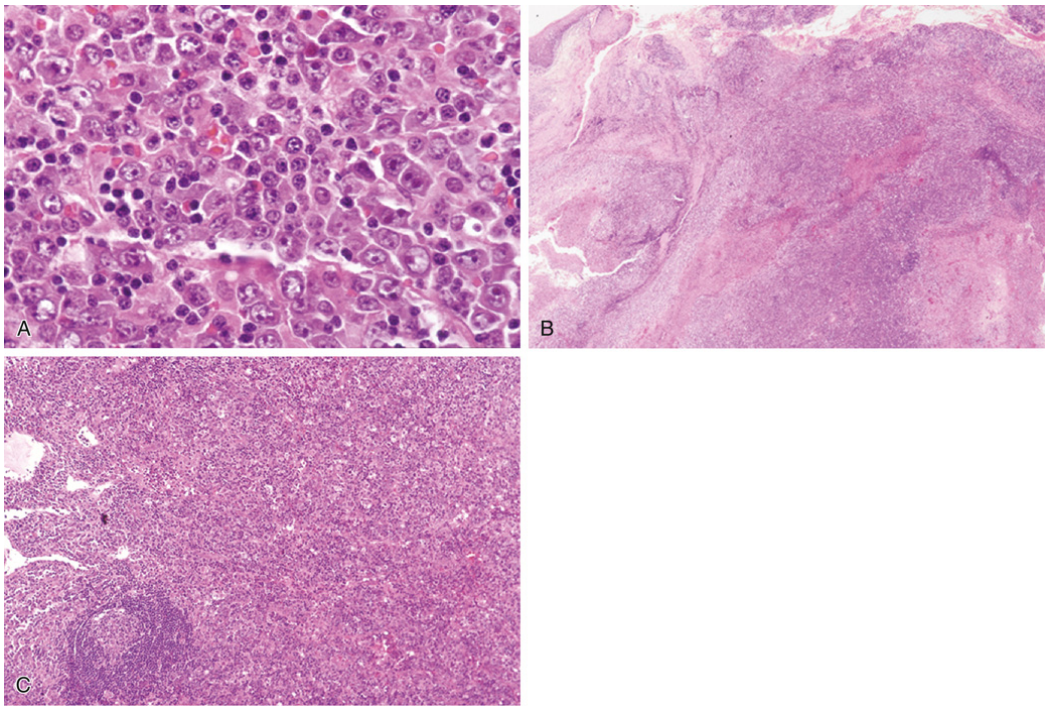

FIGURE 22-23 Infectious mononucleosis.**A,** Large lymphoid cells are present in an alarming number, raising the serious consideration of large-cell lymphoma. Usually, the large cells do not exhibit frank atypia and show a transition into recognizable plasmablasts and plasma cells. **B,** The tonsil is commonly involved and usually exhibits ulceration and necrosis. **C,** An important clue to the correct diagnosis of infectious mononucleosis is partial preservation of the normal lymph node architecture. Sinuses and lymphoid follicles are seen in the *left side of the field*.

If CD5 expression is detected on an LBCL, consideration should be given to pleomorphic variant of MCL, paraimmunoblastic variant of CLL/SLL, or DLBCL complicating CLL (Richter transformation),

which can closely resemble de novo CD5-positive DLBCL. Distinguishing features of the first two entities are described in the preceding paragraph, while Richter transformation is characterized by a known history of CLL or evidence of CLL infiltrate in the biopsy in the form of monotonous small lymphocytes admixed with prolymphocytes and paraimmunoblasts, along with co-expression of CD5 with CD23.

Large B-cell lymphomas with *IRF4* rearrangement and FL, grade 3, are both discussed in the chapter on FL and other germinal center B-cell lymphomas (**Chapter 17**). Both of these entities show a predominance of large B cells with expression of germinal center markers and can be confused with DLBCL, NOS. Small biopsies may be problematic because diffuse areas in *IRF4*-rearranged cases and expanded follicles in FL grade 3B can look misleadingly diffuse when only a small amount of tissue is available for review. A high level of suspicion is needed to exclude these entities. While IRF4/MUM1 expression can be seen in both nongerminal center DLBCL and in LBCL with *IRF4*-rearrangement, asymmetric tonsil involvement in children is typical of the latter entity.[275] Staining for follicular dendritic cell markers (CD21, CD23) can be helpful to evaluate for the meshworks typical of FL grade 3.

Plasmablastic or anaplastic plasmacytomas with large neoplastic cells may morphologically resemble DLBCL. Helpfully, the tumor cells in plasmacytomas are usually CD20 negative, whereas DLBCLs are almost always CD20 positive at presentation. A prior history of multiple myeloma or other myeloma-associated clinical and laboratory features can also be used to aid in diagnosis.[276] Other plasmablastic neoplasms such as plasmablastic lymphoma (usually

EBV-associated), anaplastic lymphoma kinase (ALK)-positive LBCL, and other entities should be excluded (see **Chapter 28** for more complete discussion).

CHL, such as the syncytial variant of nodular sclerosis or lymphocyte-depleted subtypes, and NLPBL can be difficult to distinguish from DLBCL particularly when the expected expression pattern of CD30 and CD15 are not seen. The presence of background eosinophils favors CHL, and syncytial nodular sclerosis CHL almost always shows prominent coagulative necrosis and polarizable sclerosis. Uniform strong CD20 immunoreactivity and immunoglobulin expression favor a diagnosis of DLBCL, whereas negative or heterogeneous staining for CD20 and positive EBV-LMP1 expression favor a diagnosis of CHL. Staining for the B-cell transcription factors OCT2 (POU2F2) and BOB.1 (POU2AF1) can be useful since one or the other is often lacking in classic Hodgkin lymphoma, even when CD20 is expressed, whereas both are usually expressed in DLBCL. Cases with intermediate features (gray-zone lymphoma) presenting with a mediastinal mass are classified as mediastinal gray-zone lymphoma (MGZL).

T-Cell Lymphomas

T-cell or NK-cell lymphomas are comprised of large neoplastic lymphoid cells that may be morphologically indistinguishable from DLBCL, but the distinction can usually be made by applying multiple lineage-associated markers. ALK-negative anaplastic large cell lymphoma can be particularly problematic because of lack of many T-cell markers and co-expression of other nonlineage markers. Conversely, lymphomas with plasmacytic differentiation may

aberrantly co-express T-cell markers or cytokeratins. Thus a large immunophenotyping panel is sometimes needed. Genotyping by studying immunoglobulin and TR gene rearrangement may be necessary to resolve the lineage in some cases.[33]

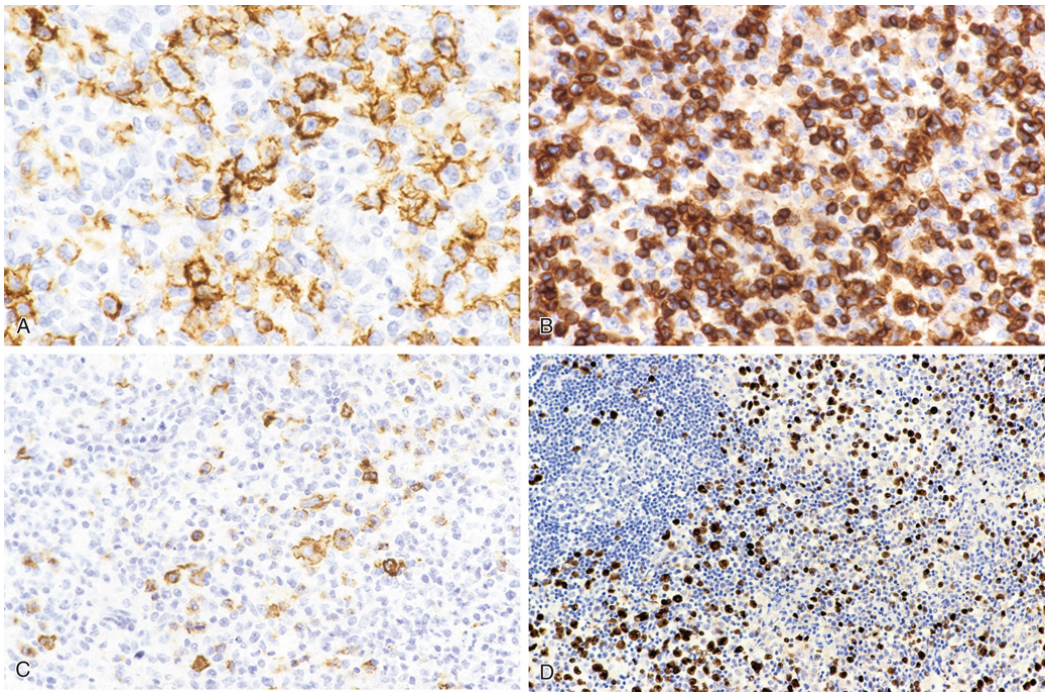

FIGURE 22-24 Immunohistochemistry of infectious mononucleosis.**A,** Although many CD20-positive cells are often present, the intensity of staining in the large cells is usually heterogeneous, indicating that some large cells are plasmablasts (weak or negative for CD20). The B cells are polytypic on staining for immunoglobulin *(not shown)*. **B,** There are often many CD3-positive cells, including some large ones. **C,** A proportion of cells stain for EBV-LMP1. **D,** A greater number show nuclear labeling for Epstein-Barr virus–encoded RNA (EBER) on in situ hybridization.

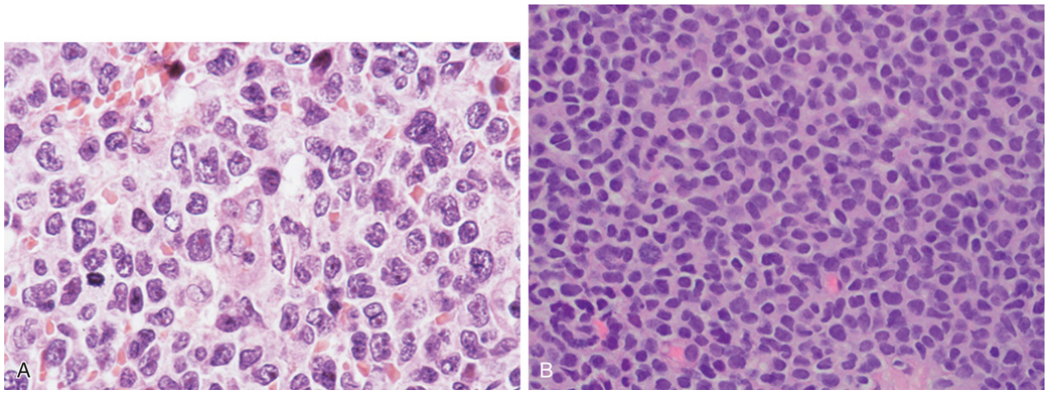

FIGURE 22-25 Pleomorphic or blastoid mantle cell lymphoma.**A,** The medium-to-large-sized pleomorphic lymphoma cells can lead to a misdiagnosis of diffuse large B-cell lymphoma. **B,** These medium-sized, irregularly shaped cells with powdery chromatin and barely discernable nucleoli are from a case of blastoid mantle cell lymphoma. Staining for CD5 and cyclin D1 are essential in such cases.

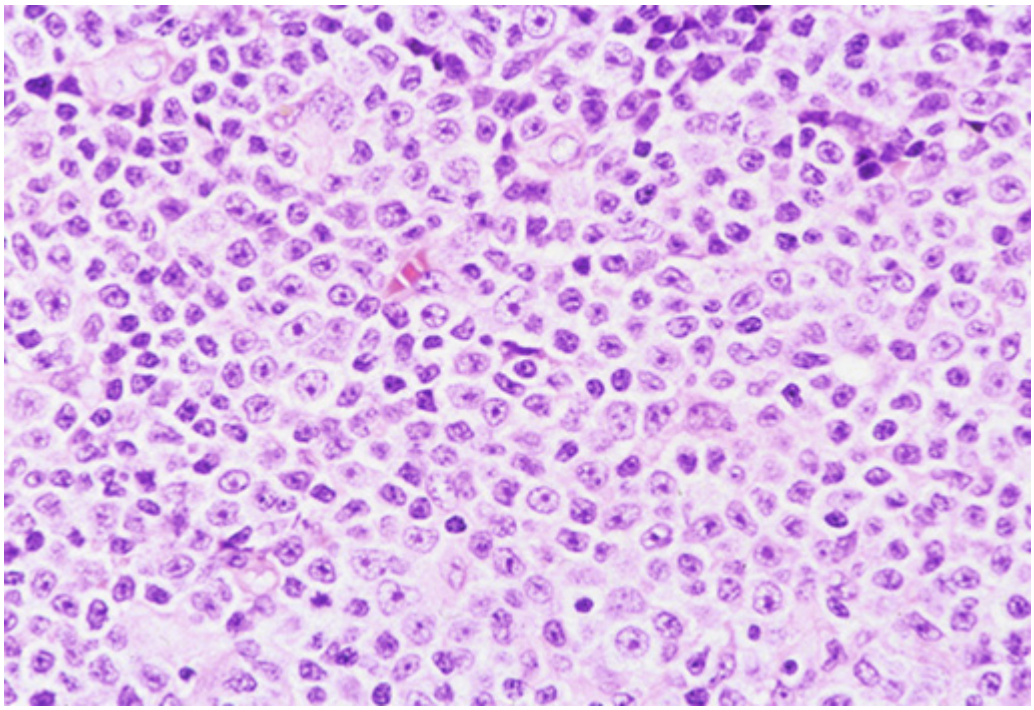

FIGURE 22-26 Paraimmunoblastic variant of chronic lymphocytic leukemia.The paraimmunoblasts differ from immunoblasts by being smaller and having paler cytoplasm. In addition, there are often admixed small lymphocytes and prolymphocytes, as characteristically seen in chronic lymphocytic leukemia.

Myeloid Neoplasm

A diagnosis of myeloid sarcoma should be suspected if there are cytoplasmic eosinophilic granules or interspersed eosinophilic myelocytes in the infiltrate. This diagnosis can be confirmed by immunostaining for myeloperoxidase, lysozyme, CD33, CD34, and CD117. Evaluation of the bone marrow may also be useful. Extramedullary hematopoietic tumors other than myeloid sarcomas

can also be mistaken for DLBCL because of the number of large cells. Clues to the correct diagnosis include the identification of megakaryocytes and erythroid normoblasts (**Fig. 22-27**).

Histiocytic sarcoma is a rare neoplasm that is sometimes part of the differential with DLBCL. The cells of histocytic sarcoma are usually larger than those of DLBCL; most important, the cytoplasm is eosinophilic rather than amphophilic or basophilic. The diagnosis requires the demonstration of histiocytic markers (e.g., CD68, CD163) and the lack of pan–B-cell markers, pan–T-cell markers, and dendritic cell markers.

Miscellaneous

Non-hematolymphoid malignancies (e.g., carcinoma, melanoma, seminoma) may be confused with DLBCL because of diffuse growth, and conversely because lymphoma can exhibit a deceptively cohesive or packeted growth pattern. Histologic features suggestive of lymphoma include highly permeative growth, amphophilic or basophilic cytoplasm, and marked folding of the nuclear membranes. Non-hematolymphoid neoplasms are consistently negative for CD45 and express their respective specific markers. However, rare cases of DLBCL have been shown to express the epithelial markers cytokeratin and epithelial membrane antigen (EMA). In addition, the "plasma cell" marker CD138 (syndecan-1) is expressed in epithelium and numerous epithelial tumors.[277] It is therefore essential to interpret the findings in context of a complete phenotype.[278,279]

T-CELL/HISTIOCYTE–RICH LARGE B-CELL LYMPHOMA

Definition

THRLBCL is associated with a prominent component of reactive T cells and usually histiocytes.[20,21] By definition, less than 10% of cells in a biopsy should consist of large atypical B cells.[280,281] THRLBCL may arise de novo. Alternatively, THRLBCL may have a close relationship to progression of NLPBL in that NLPBL may include subtotal or total areas indistinguishable from THRLBCL. In addition to morphologic and immunophenotypic overlap, similarities between these two entities have been studied by gene-expression profiling and array comparative genomic hybridization, which support a relationship between the two entities.[282,283] This distinction is discussed further under "Differential Diagnosis."

Epidemiology

The median age of patients with THRLBCL is in the 6th to 7th decades, but children may also be affected.[284] There is a male predominance (male-to-female ratio of 1.7:1).[285,286]

Etiology

No etiologic factors have been identified. The tumor microenvironment is likely engaged in cross talk with the neoplastic cells.[287] The rich T-cell infiltrate and macrophages may both contribute to the characteristic features.[288,289] Tumor-cell apoptosis, perhaps mediated by cytotoxic CD8-positive T cells, may partly explain the relatively low number of neoplastic cells.[290]

At least a proportion of cases are pathogenetically related to NLPBL[291-293] (also see "Genetics"). Some patients may have a prior history of NLPBL,[294] but such cases are often interpreted as the

diffuse growth of NLPBL signaling progression of disease rather than de novo THRLBCL.

Clinical Features

THRLBCL is predominantly a nodal disease, but extranodal sites can also be involved.[286] Compared with DLBCL, NOS, THRLBCL more frequently presents with high-stage disease (about two-thirds in stage III to IV),[286,295] and bone marrow involvement is more common (32%–62% versus 16% in DLBCL, NOS) (**Box 22-6**).[286,296,297] Liver lesions and splenomegaly are more frequent (25%).[25]

Morphology

The lymph node usually shows complete effacement of architecture by a diffuse polymorphic cellular population. The large neoplastic B cells, which should account for less than 10% of the cellular population, are dispersed singly, without the formation of discrete aggregates or sheets, in a background of small lymphocytes. The presence of even a focal component of NLPBL on morphologic or immunohistochemical assessment excludes a diagnosis of THRLBCL.

In THRLBCL, the large cells show variable cytology, including centroblasts, immunoblasts, pleomorphic large cells with irregularly folded nuclei (reminiscent of lymphocytic and histiocytic [L&H] cells of NLPBL) or even Reed-Sternberg-like cells (**Fig. 22-28**).[298] The small lymphocytes in the background are predominantly reactive T cells and are either cytologically unremarkable or mildly atypical, with a slightly larger cell size and mild nuclear folds (see **Fig. 22-**

28). In addition, variable numbers of histiocytes, epithelioid histiocytes, eosinophils, and plasma cells may be present. Fine trabecular fibrosis is common in the background.[281] In cases rich in nonepithelioid histiocytes, plasma cells and eosinophils are usually scanty.[299,300] Splenic involvement is characterized by a micronodular pattern, with the micronodules showing a cellular composition similar to that of other sites of involvement and lacking follicular dendritic cell meshworks.[298,301] A summary of THRLBCL is presented in **Box 22-6**.

Immunophenotype

The scattered large neoplastic cells express pan–B-cell markers CD19, CD20, and CD79a, and the germinal center marker BCL6. Light chain restriction is demonstrable in some cases (**Fig. 22-29**).[285,302,303] The cells should be usually negative for Hodgkin markers CD15 and CD30.[294,298,303-305] CD5 and CD10 are usually negative.[300,302] BCL2 is expressed in 40% of cases, and BCL6 in 40% to 60%.[291,300] EMA expression is variable, ranging from 3% to 100% of cases, with an overall rate of about 30%.[285,294,298,300,303,304,306]

The small cells in the background are overwhelmingly T cells (CD3-positive), predominantly the CD8-positive, TIA-1–positive, cytotoxic type (see **Fig. 22-29**).[290] In contrast to NLPBL, there are no rosettes of follicular T cells (CD57, PD-1, CXCL13, or ICOS positive) around the large neoplastic cells.[307,308] Cases of THRLBCL reported to have many T-follicular helper lymphocytes in the background may represent the diffuse variant of NLPBL.[291,300] Small reactive B cells should be rare.[300] In contrast to NLPBL, there

are no meshworks of CD21-positive follicular dendritic cells among the neoplastic large B cells.

Box 22-6 Major Diagnostic Features of T-Cell/Histiocyte–Rich Large B-Cell Lymphoma

DLBCL, Diffuse large B-cell lymphoma; *EBV,* Epstein-Barr virus; *EMA,* epithelial membrane antigen; *NLPBL,* nodular lymphocyte-predominant B-cell (Hodgkin) lymphoma; *TCR,* T-cell receptor.

Definition

- Neoplastic large B cells dispersed singly, without forming aggregates or sheets, in a background of abundant reactive T cells and usually histiocytes
- Absence of known or a recognizable component of NLPBL (which can be focal or subtle)

Clinical Features

- Age: older adults (6th to 7th decades)
- Male-to-female ratio 1.7:1
- Nodal or extranodal involvement
- Usually advanced stage at presentation (two-thirds stage III and IV)
- Bone marrow involvement very common (60%)
- Prognosis: no difference compared with comparable-stage conventional DLBCL

Morphology

- Diffuse infiltrate of scattered large neoplastic B cells that may resemble centroblasts, immunoblasts, L&H cells, or Reed-Sternberg cells
- Background cells include small T cells (which can show mild atypia), often with histiocytes, plasma cells, and eosinophils

Immunophenotype

- Large cells: pan–B-cell^{+}, CD30^{-}, CD15^{-}, EMA$^{+/-}$, BCL6$^{+/-}$
- Background small cells: CD3^{+}, CD8^{+}, TIA-1^{+}
- There should be no large neoplastic B cells residing within nodules of small B cells or meshworks of follicular dendritic cells, which would otherwise indicate a diagnosis of NLPBL

Molecular Features

- Clonally rearranged immunoglobulin genes
- Germline TCR genes
- EBV negative

The neoplastic cells are negative for EBV. The small number of cases reported to be EBV positive[281,304,309-311] are more appropriately reclassified as EBV-positive lymphomas or lymphoproliferative disorders.[20,21,312]

Genetics

THRLBCL has clonally rearranged immunoglobulin genes and germline TCR genes.[303,313-315] Hypermutated IGHV genes and ongoing somatic mutations can be demonstrated in some cases.[316,317] *BCL2* gene rearrangement is present in about 25% of cases.[285,294] Mutations in *JUNB, DUSP2, SGK1, SOCS1,* and *CREBBP* have been found in these tumors similar to NLPBL, reinforcing the relationship of both entities.[318]

Earlier comparative genomic hybridization of microdissected tumor cells showed similarities and differences in THRLBCL and NLPBL.[319] More recently, array comparative genomic hybridization analysis demonstrated that gains of 2p16.1 and losses of 2p11.2 and 9p11.2 are commonly observed in both THRLBCL and NLPBL[283] while gene expression profiling of microdissected tumor cells of THRLBCL and NLPBL do not show clear-cut differences.[293] These combined molecular findings support a link, but not complete overlap, between the two entities. Currently, it is thought that THRLBCL and NLPBL likely represent part of a disease spectrum with different clinical behavior, which may be influenced by the differences in the microenvironment of the lymphomas, possibly related to the immune status of the patients.[283,293]

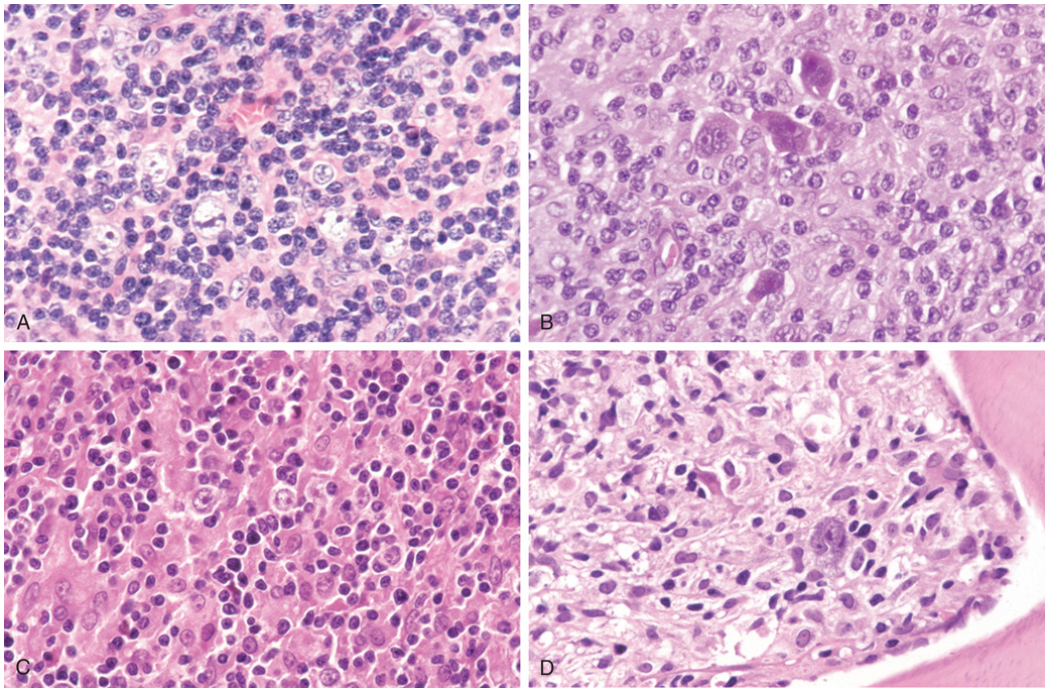

FIGURE 22-28 T-cell/histiocyte–rich large B-cell lymphoma.**A,** Large lymphoid cells are scattered singly among small lymphocytes. **B,** Large cells, some resembling Reed-Sternberg cells, occur in a background of slightly activated small lymphoid cells. **C,** This example is rich in small T lymphocytes and histiocytes in the background. **D,** T-cell/histiocyte–rich large B-cell lymphoma with bone marrow involvement. Note the scattered large atypical cells in a background of small cytologically unremarkable lymphoid cells and histiocytes.

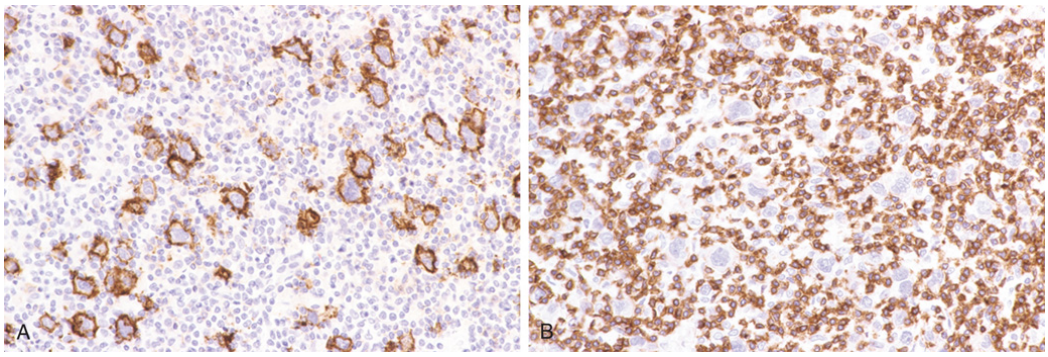

FIGURE 22-29 Immunohistochemistry of T-cell/histiocyte–rich large B-cell lymphoma.**A,** CD20 immunostain selectively highlights the dispersed large cells. **B,** Numerous small CD3-positive T lymphocytes are present in the background.

Postulated Cell of Origin

Demonstration of a hypermutated immunoglobulin gene with ongoing somatic mutations and *BCL2* rearrangement in some cases, and expression of BCL6, altogether support a germinal-center stage of differentiation.[20,21,316,317]

Clinical Course

In an examination of US cases from 2010 to 2015, the 5-year OS using rituximab-based immunochemotherapy was 66%; adjusting for socioeconomic variables, THRLBCL was associated with a better survival than DLBCL, NOS (adjusted hazard ratio, 0.80). Prognostic features included age, comorbidity index, and extranodal primary site, but not stage. Adjusted odds of prior NLPBL were 18.2 times higher for THRLBCL than DLBCL, NOS.[320] Clinical outcomes for THRLBCL similar to DLBCL, NOS were also reported from Asia.[321]

Cases rich in histiocytes may have a poorer prognosis,[297] and a primary cutaneous counterpart with a more favorable outcome has been reported.[322]

Differential Diagnosis

The main differential diagnoses and their distinguishing features are listed in **Table 22-6**. In some examples of THRLBCL, the large cells resemble reactive immunoblasts, making it difficult to distinguish from reactive lymphoid hyperplasia. In THRLBCL, definite atypia (e.g., enlarged nuclei, irregular nuclear folding) can usually be recognized in at least a small proportion of the large cells after a careful search, and the pattern of uniform scattering of solitary large cells in a small lymphoid cell background is very unusual for a reactive process. Furthermore, in reactive lymphoid hyperplasia, the large lymphoid cells more often occur in patchy aggregates, show transition to plasmablasts and plasma cells, exhibit heterogeneous staining for CD20 owing to the presence of B cells in different stages of maturation, and show polytypic staining for immunoglobulin light chains.

In NLPBL with an extensive diffuse component, the presence of scattered large LP cells with a B-cell phenotype in a background of small T lymphocytes is indistinguishable from THRLBCL.[304] Patients with NLPBL are younger (30–50 years), and most patients (80%–95%) present with early-stage (I–II) disease.[323] Histologically, a nodular pattern is usually identified at least focally and if not morphologically obvious can sometimes be detected using stains for follicular dendritic cell markers (such as CD21 or CD23). Often, follicular T-cell rosettes around the L&H tumor cells can be

demonstrated by CD57 or PD-1.[293,307] Although the small lymphocytes within the nodules of NLPBL are mostly B cells, those in the diffuse areas are mostly T cells. The T cells in NLPBL infrequently express the cytotoxic marker TIA-1.[304]

Table 22-6

EBV, Epstein-Barr virus; *L&H,* lymphocytic and histiocytic; *TCR,* T-cell receptor.

The lymphocyte-rich and mixed cellularity types of CHL can simulate THRLBCL.[309,324,325] Reed-Sternberg cells are either negative for pan–B-cell markers or show heterogeneous staining if positive, are frequently CD30 positive and CD15 positive, and are more likely to harbor EBV.

Lymphomatoid granulomatosis also features large, atypical B cells in a background of reactive T cells, but it always presents in extranodal sites (most commonly lung and skin), and EBV is almost always positive (see **Chapter 28**).

THRLBCL may also be confused with peripheral T-cell lymphoma (PTCL) because the activated T cells in the background of THRLBCL can show mild atypia. In PTCL, the T cells show a more prominent degree of cytologic atypia, and the atypia involves lymphoid cells of various sizes. The larger PTCL cells within the infiltrate do not stand out distinctly as a separate population, as the large B cells do in THRLBCL, and there is a transition with the smaller atypical cells. Immunophenotypically, the large, atypical cells of PTCL express pan–T-cell rather than pan–B-cell markers. Nonetheless, confusion can arise because some PTCLs, especially angioimmunoblastic T-cell lymphoma, can be accompanied by a reactive large B cell

proliferation, which is often EBV driven.[326-329] Careful correlation between immunostaining and morphology reveals that although some large, atypical cells are CD20 positive, most of the atypical medium-sized and large cells are CD20 negative and CD3 positive. Genotyping is confirmatory in difficult cases because THRLBCL has rearranged immunoglobulin genes,[303,313-315,330] whereas PTCL has rearranged TCR genes.

PRIMARY MEDIASTINAL LARGE B-CELL LYMPHOMA

Definition

PMBL is a distinct subtype of DLBCL of putative thymic B-cell origin. By definition, the major bulk of tumor is confined to the anterior superior mediastinum at presentation.[331,332]

Epidemiology

PMBL accounts for 2.4% of all non-Hodgkin lymphomas.[3,333] Most patients are young adults (median age, 37 years),[3,334-336] but children can also be affected.[337] There is a female predominance,[3,334-336] with a female-to-male ratio of 2:1.

Clinical Features

Patients present with symptoms related to the large anterior mediastinal mass, such as superior vena cava obstruction, dyspnea, and chest discomfort.[338-341] Most patients present with early-stage disease (70%–80% stages I and II).[342] The tumor can invade the chest wall, sternum, pericardium, pleura, and lung.[340,343-346] There can sometimes be supraclavicular lymphadenopathy. Involvement

outside of the thorax is observed in ~10% of patients, with sites including the kidneys, adrenal glands, and bone marrow.[342,346] These sites, along with the CNS, can be involved at the time of relapse.

Morphology

The tumor exhibits a diffuse infiltrate of large- or medium-sized lymphoma cells with a highly variable appearance. The lymphoma cells can have a centroblastic, immunoblastic, anaplastic, unclassifiable, or Reed-Sternberg–like appearance. The nuclei are round or multilobated. Cytoplasm is often abundant and not uncommonly (40% of cases) shows clearing (Figs. **22-30** and **22-31**).[324,325,338,340,344,346,347] Sometimes the lymphoma cells assume a spindly morphology (see **Fig. 22-31**). Rare cases exhibit a marked tropism for preexisting GCs.[348]

Sclerosis is common, ranging from delicate collagen fibers surrounding individual or groups of lymphoma cells ("compartmentalizing" or "alveolar") to broad septa of dense collagen (**Fig. 22-32**).[338,343,346] Occasionally there is identifiable remnant thymic epithelium, which can show atrophy, hyperplasia, or cystic change (**Fig. 22-33**).[344,349] A summary of PMBL is presented in **Box 22-7**.

Immunophenotype

PMBL expresses pan–B-cell markers.[343,347,350-352] However, most cases do not express surface or cytoplasmic immunoglobulin, despite expression of CD79a (a component of a heterodimer associated with surface immunoglobulin) and the immunoglobulin transactivating

factors OCT-2 and BOB.1.[325,350,352-355] Because messenger RNA transcripts of switched immunoglobulin heavy chain can be detected in PMBL,[356] the reason behind the immunoglobulin-negative immunophenotype remains unclear, but may involve downregulation of intronic heavy chain enhancer.[357] The tumor also shows low or absent expression of MHC class I and II molecules.[358,359]

PMBL is negative for CD21 and frequently expresses CD23 (70% of cases), similar to the asteroid B cells normally found in the medulla of the thymus.[351-353,360-363] CD10, BCL6, and CD30 are expressed in ~25%, ~60%, and ~70% of cases, respectively.[355,364-366] Rare cases expressing human chorionic gonadotropin, which could cause confusion with mediastinal germ cell tumors, have been reported.[367]

MAL gene (on chromosome 2q) expression, which can be demonstrated by molecular methods or immunohistochemistry, occurs in 70% of cases but is extremely rare in other DLBCLs (**Fig. 22-34**).[368,369] Other immunohistochemical markers that have been reported to show preferential expression in PMBL compared with DLBCL, NOS include CD200 (94% versus 7%),[370] TNFAIP2 (87% versus 4%),[371] PD-L2 (CD273) (72% versus 3%),[372] and combined nuclear REL expression and cytoplasmic TRAF1 expression (53% versus 2%).[373]

Genetics

PMBL shows clonally rearranged immunoglobulin heavy chain and light chain genes and germline TCR genes.[374] There is no *CCND1* rearrangement and *BCL2* rearrangement is rare; *BCL6* rearrangement occurs in only ~5% of cases, whereas *BCL6* mutations

are reported in up to 70% of cases.[255,355,375-377] Rearrangements or point mutations in *MYC* have been detected in occasional cases.[376,378] EBV is almost always negative.[344,376,378] For the rare occurrence of familial clustering PMBL, *KMT2A* may be a candidate predisposition gene.[379]

PMBL shows a unique gene-expression profile that is much closer to that of CHL than DLBCL, NOS.[380,381] With PMBL being a clinicopathologic diagnosis, these gene expression signatures may be useful in the differential with DLBCL, NOS where the anterior mediastinum is involved.[382] The hallmarks of PMBL are JAK/STAT signaling, activation of NF-κB, and immune evasion.[359,383]

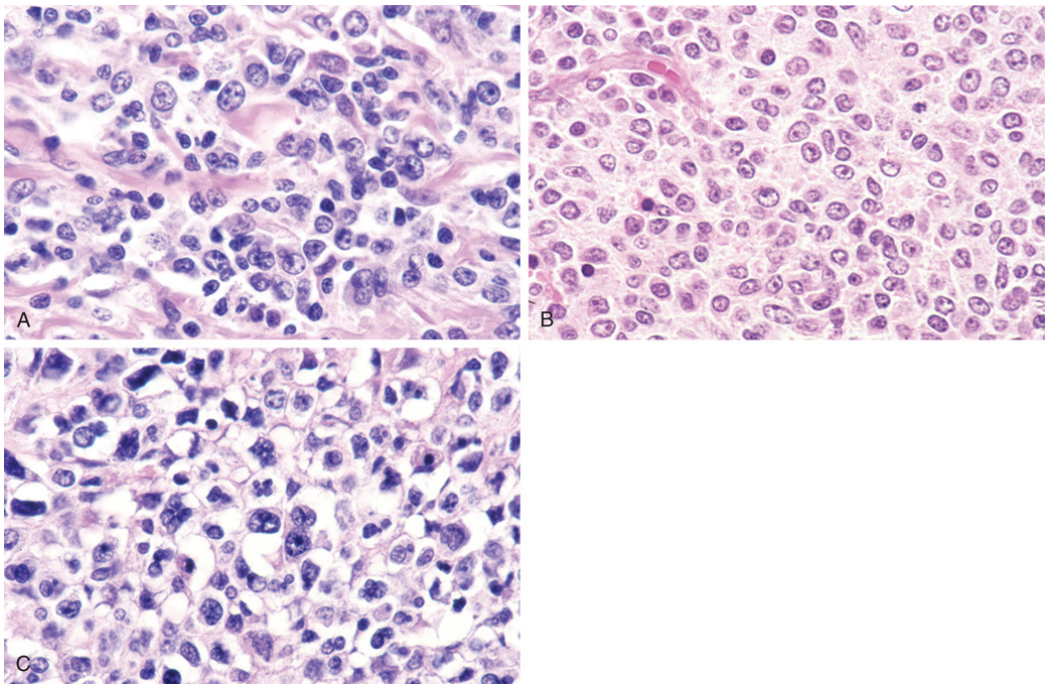

FIGURE 22-30 Primary mediastinal large B-cell lymphoma cytologic spectrum.**A,** The large cells are similar to the centroblasts seen in nodal diffuse large B-cell lymphoma. **B,** Not uncommonly, the lymphoma cells have an appreciable amount of cytoplasm as demonstrated by the widely spaced cells. **C,** Nuclear multilobation and clear cytoplasm are common findings.

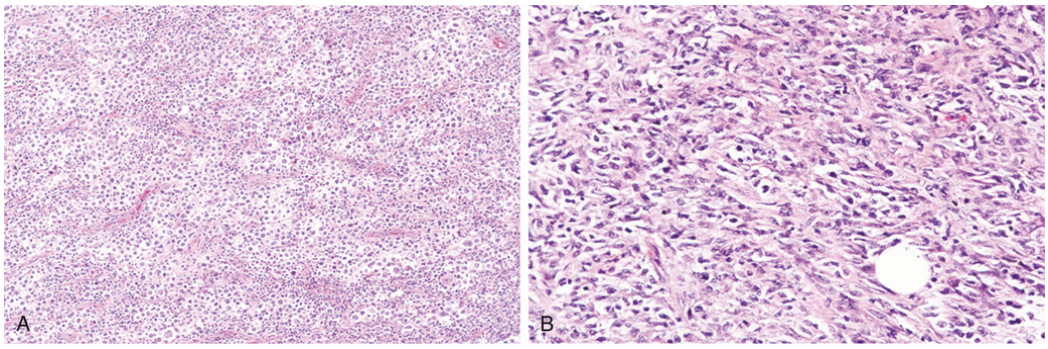

FIGURE 22-31 Primary mediastinal large B-cell lymphoma: unusual appearances.**A,** The presence of clear cells demarcated by fibrovascular septa produces an appearance reminiscent of germinoma. **B,** Spindly lymphoma cells are sometimes prominent.

The JAK-STAT pathway is activated as a result of *JAK2* (9q24) amplification, activating mutation of *STAT6,* loss-of-function mutation of *SOCS1* (which normally inhibits JAK phosphorylation and targets phosphorylated JAK for degradation), activating mutations of *IL4R,* and inactivating mutation of *PTPN1* (negative regulator).[377,384-387] The NF-κB pathway is constitutively activated as a result of *REL* (2p16) amplification, destructive and biallelic mutations in *TNFAIP3* (encoding A20, a tumor-suppressor gene that inhibits NF-κB signaling), and mutation of *NFKBIE*.[365,377,387-390] Immune privilege is mediated by *CIITA* gene (master transcriptional regulator of MHC class II expression) rearrangement with various gene partners causing reduction of MHC class II expression, mutations in *B2M,* deletions of MHC class I and II loci, mutations in *CD58,* and amplification and translocation of *CD274* and *PDCD1LG2* genes (resulting in overexpression of PD-L1 and PD-L2, which interact with PD1 on T lymphocytes to cause T-cell anergy).[147,377,387]

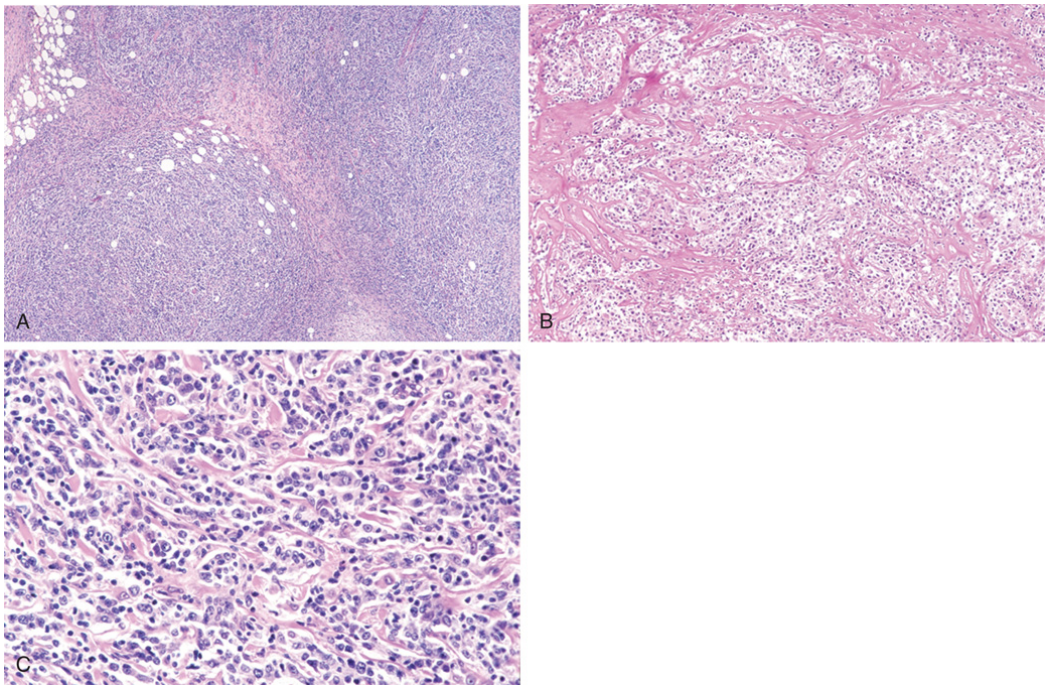

FIGURE 22-32 Primary mediastinal large B-cell lymphoma: patterns of sclerosis.**A,** Broad sclerotic bands traverse the tumor to produce large tumor nodules. **B,** Thinner sclerotic bands demarcate the tumor into packets. **C,** Delicate collagen fibrils are found within the tumor.

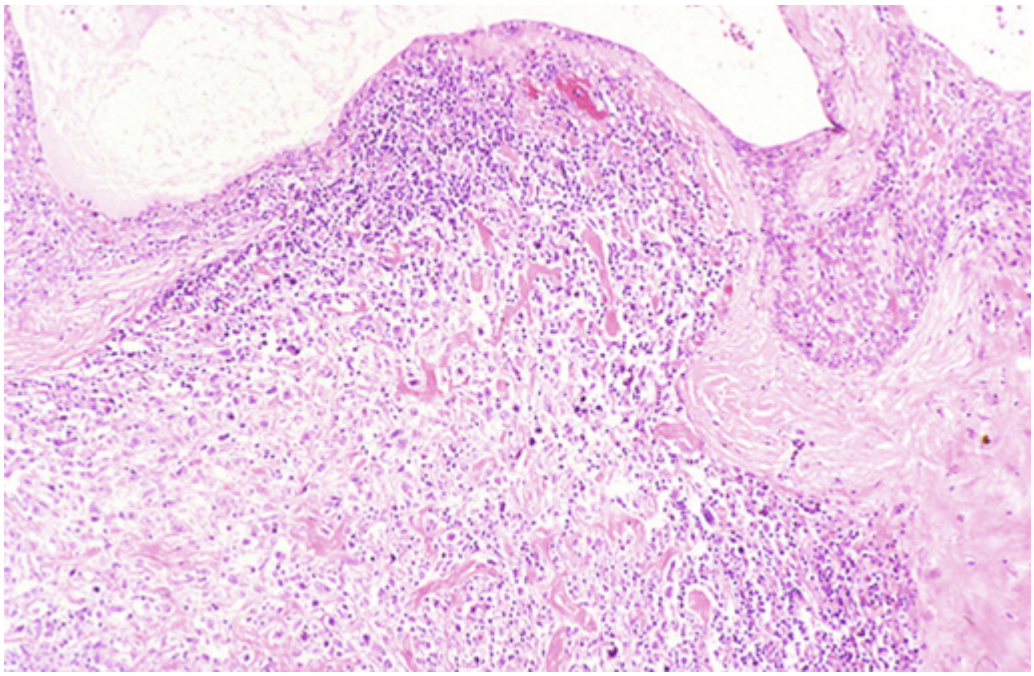

FIGURE 22-33 Primary mediastinal large B-cell lymphoma.In this example, there is proliferation of the residual thymic epithelium and formation of cysts lined by thymic epithelium.

Postulated Cell of Origin

Addis and Isaacson first suggested a thymic B-cell origin for PMBL based on the tumor location, frequent lack of nodal involvement, and presence of residual thymic tissue in some cases.[343] Subsequently, a distinctive population of CD21-negative thymic B cells was identified in the normal thymus, and these cells (particularly the population with asteroid morphology) are considered the normal counterpart for PMBL.[360,361,363]

Clinical Course

The standard treatment is multiagent chemotherapy and rituximab, with or without radiotherapy, resulting in a 2-year PFS of ~80% or greater (reviewed by Savage[342]). In the 10% to 20% of patients that experience treatment failure, outcomes are poor. At relapse, PD1 inhibitors (alone or in combination with brentuximab vedotin) and CAR-T therapy have shown promising results.[198,200,391-393]

Reported poor prognostic indicators include pleural effusion, pericardial effusion, increased number of involved extranodal sites, high serum lactate dehydrogenase level, low performance score, and high IPI score,[345,394-397] though not confirmed in more recent studies.[398,399] Loss of the MHC class II gene and protein expression is a poor prognostic indicator.[400] Results of the end-of-treatment PET scan are strongly prognostic, with Deauville 5 being associated with very poor PFS (20%–30% at 2 years).[401-403]

At the time of recurrence, PMBL cases have a tendency to spread to unusual extranodal sites, such as the kidney, CNS, adrenal gland, liver, pancreas, gastrointestinal tract, and ovary,[334,336,404,405] and the extranodal predilection may be partly explained by its chemokine receptor profile, which differs from DLBCL, NOS and CHL.[406]

Box 22-7 Major Diagnostic Features of Primary Mediastinal Large B-Cell Lymphoma

DLBCL, NOS, Diffuse large B-cell lymphoma, not otherwise specified; *EBV,* Epstein-Barr virus; *MHC,* major histocompatibility complex.

Distinctive Clinical Features (Versus DLBCL, NOS)

- Young adult: median age 37 years (versus 64 years)
- Female predominance: male-to-female ratio 1:2 (versus 1.2:1)
- Symptoms related to anterior mediastinal mass (e.g., superior vena cava obstruction, dyspnea)
- Bulky disease (>10 cm) in 52% of cases (versus 30%)
- Early stage (I and II) disease in 66% of cases (versus 54%)
- Marrow involvement very rare (3% versus 16%)
- Relapse tends to occur more frequently in extranodal sites compared with time of diagnosis (e.g., gastrointestinal tract, kidney, adrenal gland, ovary, central nervous system)

Morphology

- Large- or medium-sized lymphoma cells
- Clear cell change, compartmentalizing sclerosis more common than in DLBCL, NOS

Immunophenotype

- Pan-B positive, CD3 negative
- Surface immunoglobulin frequently negative
- BCL6 positive in ~60%
- CD10 positive in ~25%
- CD23 positive in ~70%
- CD30 positive in ~70%
- MAL in ~70%
- PD-L1/2 in ~70%
- EBV negative

- Deficient MHC molecule expression

Molecular Features

- Clonally rearranged immunoglobulin genes
- *BCL2* and *BCL6* genes usually not rearranged
- Unique gene-expression profile closer to that of classic Hodgkin lymphoma than DLBCL, NOS
- Activation of JAK-STAT pathway (*JAK2* amplification, *STAT6* and *IL4R* mutations, inactivating mutation of *SOCS1* and *PTPN1*)
- Activation of NF-κB pathway (*REL* amplification at 2p16.1, loss of *TNFAIP3,* mutations in *NFKBIE*)
- Immune privilege (*CIITA* gene translocation leading to loss of MHC class II expression, mutations in *B2M* and *CD58, CD274* and *PDCD1LG2* [encoding for PD-L1 and PD-L2, respectively] amplification and translocation)

Differential Diagnosis

By definition, the tumor bulk in PMBL is in the anterior mediastinum, thus excluding other nodal or extranodal DLBCLs (DLBCL, NOS) that secondarily involve the mediastinum. In some PMBL cases, the presenting lymph node may be outside the mediastinum. In these cases, characteristic histologic (cytology, fine compartmentalizing sclerosis) and immunophenotypic features of PMBL (MAL, PDL2) should be evaluated in comparison to DLBCL. In addition, a gene expression profiling assay to distinguish DLBCL from PMBL has been described and is in clinical use in select

centers.[382] The main differential diagnoses are listed in **Table 22-7** (see also “Pearls and Pitfalls”).

Another important differential diagnosis for PMBL is nodular sclerosis CHL. Similarities include occurrence in young patients, predominant anterior mediastinal location, large tumor cells, and sclerosis. The problem in differential diagnosis is compounded by the fact that some PMBLs express CD30, and some cases of nodular sclerosis CHL can express pan–B-cell markers. Nodular sclerosis CHL is associated with an inflammatory background, often rich in eosinophils, and the tumor cells express CD30 and CD15 but not CD45. Although pan–B-cell markers may be expressed in Reed-Sternberg cells, the expression is usually heterogeneous, in contrast to the uniformly strong staining in PMBL. Reed-Sternberg cells are usually negative for the immunoglobulin transactivating factors OCT-2 and BOB.1, contrasting with their consistent expression in PMBL.[355,407] EBV, when present, would favor a diagnosis of CHL over PMBL.[332] Composite or metachronous cases of PMBL and nodular sclerosis CHL have been described,[334,408-410] with demonstration of the same clone in the two different components in at least some cases.[410] The link between PMBL and CHL is further supported by similarities in the gene-expression profiles of the two entities[380,381] and the existence of occasional cases of MAL-expressing nodular sclerosis CHL.[369,411]

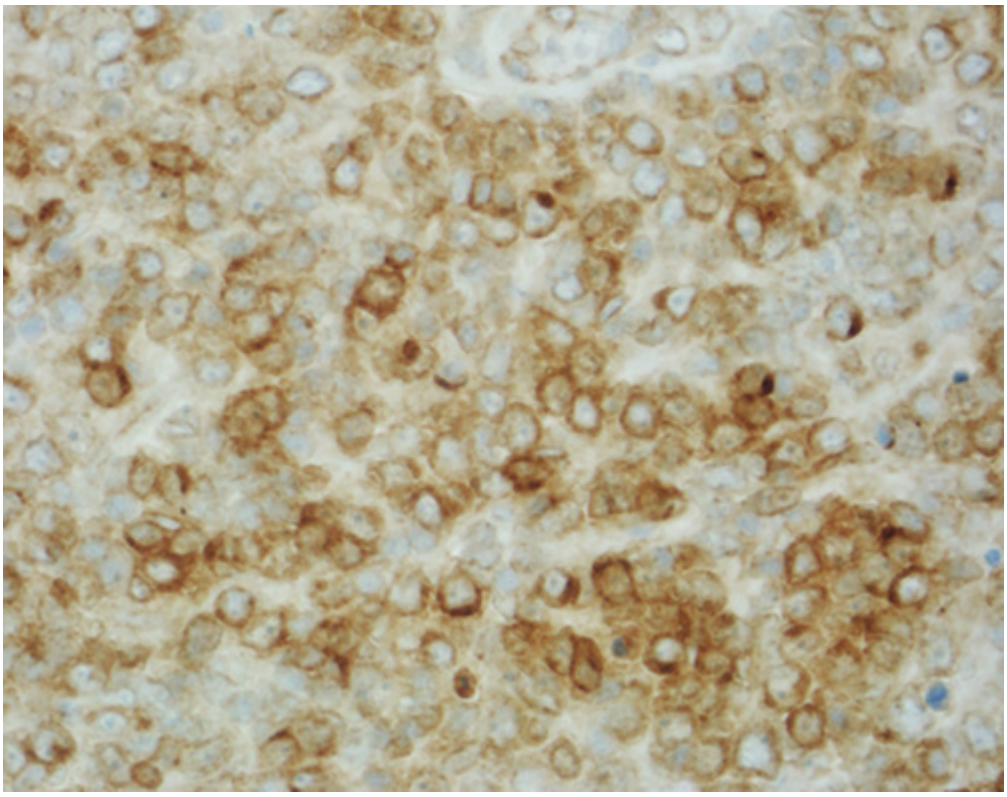

FIGURE 22-34 Primary mediastinal large B-cell lymphoma.The tumor cells show strong cytoplasmic and membrane staining for MAL, a marker frequently expressed in this entity.

Cases with overlapping histologic features or transitional immunophenotype that lie between PMBL and CHL are currently categorized as MGZL and are fully discussed in the chapter on Hodgkin lymphoma (**Chapter 28**).[20,21,410,412,413]

Tumors with the gene expression of PMBL have been observed that present without evidence of mediastinal involvement.[414,415] While these tumors share the expression and sometimes histologic features of PMBL, the genetic mechanisms by which they arrive at these are distinct and a diagnosis of DLBCL, NOS is usually favored.[416]

Anaplastic large cell lymphoma shares similarities with PMBL, including the presence of many large lymphoid cells and CD30 immunoreactivity. However, the former has a T-cell phenotype (PAX5 negative), often with expression of cytotoxic markers, and may express ALK.[417]

PMBL can mimic mediastinal seminoma when there is tumor packeting and the presence of clear cells. However, seminoma occurs exclusively in males, shows round but not multilobated nuclei, and expresses CD117 and OCT3/4, but not CD45 and pan–B-cell markers.

Table 22-7

Differential Diagnosis of Primary Mediastinal Large B-Cell Lymphoma (PMBL)

Entity	Features Favoring Diagnosis of That Entity	Features Favoring Diagnosis of PMBL
DLBCL, NOS	Accompanied by disease in sites other than anterior mediastinum	Predominant mass in anterior mediastinum at presentation CD23 or MAL expression Surface immunoglobulin expression commonly absent
Nodular sclerosis Hodgkin lymphoma, syncytial variant	Many eosinophils, histiocytes, and neutrophils in background Necrosis common within dense sheets of large tumor cells	Clear cell change common Fine sclerosis $CD45^{+}$, pan–B-$cell^{+}$, $CD30^{+/-}$, $CD15^{-}$, $OCT\text{-}2^{+}$, $BOB.1^{+}$ EBV almost always negative

Entity	Features Favoring Diagnosis of That Entity	Features Favoring Diagnosis of PMBL
	Broad bands of polarizable sclerosis $CD45^{-}$, $CD30^{+}$, $CD15^{+/-}$, pan–B-$cell^{-/+}$ (heterogeneous if positive), $OCT\text{-}2^{-}$, $BOB.1^{-}$ EBV^{+} in >35%	
Anaplastic large cell lymphoma	Hallmark cells Pan–B-$cell^{-}$, pan–T-$cell^{+/-}$ $EMA^{+/-}$, $ALK^{+/-}$ Cytotoxic $markers^{+/-}$	Sclerosis much more common Pan–B-$cell^{+}$, pan–T-$cell^{-}$ EMA^{-}
Mediastinal seminoma	Almost exclusively male Nuclei often round $CD45^{-}$, $OCT\text{-}3/4^{+}$, $CD117^{+}$	Although cells may have clear cytoplasm, nuclei are often lobated or folded $CD45^{+}$, pan–B-$cell^{+}$, $CD117^{-}$

Entity	Features Favoring Diagnosis of That Entity	Features Favoring Diagnosis of PMBL
Thymic carcinoma	Cohesive growth; sharp interface with desmoplastic stroma May exhibit squamous or squamoid features Cytokeratin +	Although tumor may show packeting pattern, diffuse permeative growth in at least some areas Cytokeratin –, $CD20^{+}$
Thymic carcinoid	Nests of tumor cells separated by rich vasculature May form rosettes Cytokeratin +, neuroendocrine markers +	Although tumor may show packeting pattern, sclerotic septa are relatively avascular Cytokeratin –, $CD45^{+}$, neuroendocrine markers –

ALK, Anaplastic lymphoma kinase; *DLBCL, NOS,* diffuse large B-cell lymphoma, not otherwise specified; *EBV,* Epstein-Barr virus; *EMA,* epithelial membrane antigen.

Thymic carcinoma and neuroendocrine tumors may enter into the differential diagnosis in small biopsy samples. Both express cytokeratin and are negative for CD45 and pan–B-cell markers.

INTRAVASCULAR LARGE B-CELL LYMPHOMA

Definition

IVLBCL is an aggressive disease in which the lymphoma cells reside predominantly or exclusively within the lumens of small blood vessels, with no or few circulating neoplastic cells in the peripheral blood.[418,419] Occasional cases show extravascular involvement. The degree to which extravascular involvement is allowed into the diagnostic category of IVLBCL and when cases should be classified as DLBCL, NOS with significant intravascular involvement is currently under consideration.[420,421] DLBCL, NOS with intravascular involvement has been reported as a poor prognostic factor, but is not considered IVLBCL at this time.[422-424] Three variants of IVLBCL are recognized: classic, hemophagocytic, and primary cutaneous.[425] Although classical and hemophagocytic variants are seen more frequently in Western and Asian countries, respectively, they can be seen in patients from both geographic regions.[425-427]

Epidemiology

IVLBCL is a rare lymphoma occurring predominantly in older patients in the 6th to 7th decades.[428] In Asian countries, the frequency of IVLBCL among all non-Hodgkin lymphomas ranges from 0.24% in Japan to 0.9% in Thailand.[429] A population-based study in North America indicated an incidence of 0.095

(case/1,000,000) with a median age of 70 years. The median 1-year OS was 66.2%, the 3-year OS was 51.8%, and the 5-year OS was 46.3%, which was comparable to DLBCL, NOS.[430]

Etiology

There is no known etiologic factor for IVLBCL. The lymphoma cells' propensity to be localized in the lumens of blood vessels may be partly explained by the lack of expression of CD29 (β_1-integrin) and CD54 (ICAM-1), both of which are important for transvascular lymphocyte migration, and the CD40-CD40L activation of B cells.[431,432]

Clinical Features

IVLBCL can involve any organ, but most commonly involves the CNS, skin, kidney, lung, adrenal glands, and liver.[428,433,434] Patients commonly present with fever; non-specific, nonlocalizing neurologic symptoms; or skin lesions. The neurologic symptoms are often bizarre, owing to the presence of multiple sites of infarct resulting from vascular occlusion. Patients may have multifocal cerebrovascular events, spinal cord and roots lesions, subacute encephalopathy, and peripheral or cranial neuropathy.[435] The cutaneous manifestations are non-specific, most commonly consisting of nodular, subcutaneous, firm masses or plaques, with or without hemorrhage. Overlying telangiectasia may be prominent, and there may be ulceration. The trunk and extremities are frequently involved sites. The rare patients who have disease limited to the skin (cutaneous variant) seem to have a better outcome.[434]

Uncommon presentations include interstitial lung disease,[436] pulmonary small vessel disease,[437] adrenal insufficiency,[438,439] minimal change disease of the kidney,[440] thrombotic microangiopathy,[441] and epididymal mass.[442] IVLBCL may be diagnosed by renal biopsy,[443,444] testicular biopsy,[445] bone marrow aspiration and biopsy,[82] nerve and muscle biopsy,[446] or lacrimal gland biopsy,[447] and it may be an incidental finding in the prostate.[448,449] Association with autoimmune diseases has been observed in some patients,[433] as has acquired immunodeficiency syndrome (AIDS), methotrexate treatment association, or silicone breast implant association.[450-453] IVLBCL may involve preexisting tumors, such as hemangioma,[454] lymphangioma,[455] angiolipoma,[456] meningioma,[457] renal cell carcinoma,[458] and Kaposi sarcoma,[451] or may occur as a clonally related Richter transformation from a preexisting CLL.[459] A rare case of transmission from a solid-organ transplant donor to multiple recipients has been reported.[460]

Histologic bone marrow involvement is reported as 61.5% in a small case series.[461] More frequent demonstration of immunoglobulin gene rearrangement by polymerase chain reaction in histologically negative bone marrow samples has been described, suggesting that subtle bone marrow involvement is common.[462]

The hemophagocytic syndrome–associated variant occurs mostly in Asians (most commonly Japanese),[426,463-467] and is uncommon in Western countries.[468-471] These patients are older adults and present with fever, hepatosplenomegaly, hemophagocytic syndrome with anemia and thrombocytopenia, bone marrow involvement, and disseminated intravascular coagulation. They usually lack

lymphadenopathy, mass lesions, or skin lesions. There is no association with EBV or human T-lymphotropic virus-1.[463,466]

Morphology

Histologically, large- or medium-sized lymphoma cells are found within the lumens of small or intermediate-sized blood vessels (**Fig. 22-35**).[433,472] They can have a centroblastic, immunoblastic, or unclassifiable appearance. They often fill up the vascular lumens, but can sometimes palisade along the luminal side, mimicking angiosarcoma (**Fig. 22-36**). The cells can appear deceptively cohesive, resembling islands of carcinoma (**Fig. 22-37**). The lymphoma cells may be entrapped within organized fibrin thrombi, and there may be superimposed florid endothelial hyperplasia. The vascular occlusion can result in tissue infarction and hemorrhage (**Fig. 22-38**). Some cases may have an extravascular component.[421,428,433,472]

The lymphomatous involvement is usually obvious morphologically but can be so focal and subtle that the neoplastic cells become evident only on immunostaining for B-cell and endothelial markers.

Immunophenotype

The lymphoma cells express CD45 and pan–B-cell markers (**Fig. 22-39**).[428,472] A small proportion of cases express CD5, CD10, and BCL6 (22% each).[81,82,428,455] Most cases are non-GCB by immunohistochemistry or gene-expression profiling studies.[461,473,474] Expression of the oncofetal protein insulin-like growth factor 2 mRNA binding protein-3 (IMP3) is enriched in

IVLBCL and was reported as a potentially useful adjunct test in diagnosis.[475]

CD5 expression is not associated with any specific clinical features. Exceptional cases reportedly express myeloperoxidase or cytokeratin.[476,477] The immunophenotype of the hemophagocytic syndrome–associated variant is similar to that of the usual IVLBCL.[426] PD-L1 is frequently expressed, is associated with a poor prognosis, and may have therapeutic implications with regard to targeted immunotherapy.[478,479] Loss of major histocompatibility class I and II protein expression may be another strategy related to immune escape.[480] Both MYC and BCL2 protein expression have been described.[481]

Genetics

IVLBCL shows clonal immunoglobulin gene rearrangements.[482,483] The *BCL2* gene is not translocated,[428] but occasional cases with *BCL6, IRF4* or *IGH*::*CCND1* translocation have been described.[421,484,485] Cytogenetic structural abnormalities involving most frequently 6q13 and 8p11.2, and 19q13, 14q32, and chromosome 18 have been reported. On average 4.4 chromosomal gains and losses were detected per case; some cases have complex (more than three clonal aberrations) karyotypes, and some have normal karyotypes. Marker chromosomes were also identified.[426,465,486] Frequent genetic alterations in immune checkpoint-related genes and *MYD88* and *CD79B* mutations (these two latter genes also mutated in ABC-DLBCL) have been reported.[148,480,487] Rearrangements of *CD274/PDCD1LG2*

involving the 3′UTR are frequently observed and result in PD-L1/PD-L2 overexpression.[148]

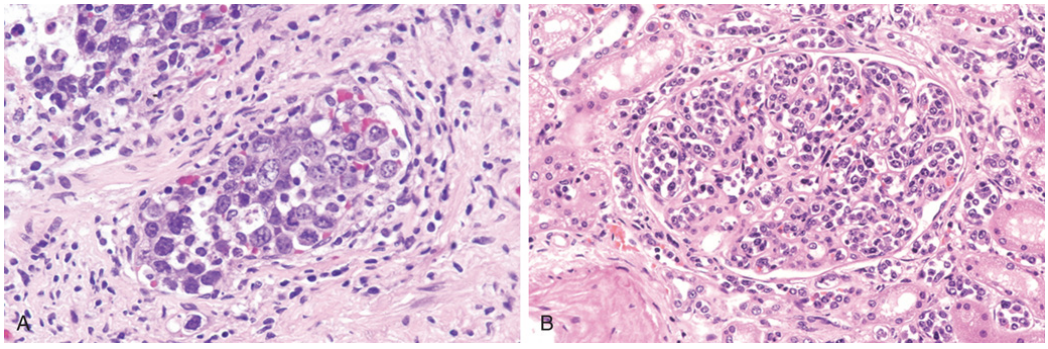

FIGURE 22-35 Intravascular large B-cell lymphoma.**A,** The noncohesive lymphoma cells are confined within medium-sized blood vessels. **B,** Lymphoma cells distend the capillaries of the glomeruli and the renal parenchyma.

EBV is negative,[428] except in patients living with AIDS.[451] While those cases with coinfection by HHV-8 probably represent unusual presentation of primary effusion lymphoma,[488,489] rare HHV-8–positive EBV-negative cases have also been described.[490]

Postulated Cell of Origin

IVLBCLs are derived from peripheral B cells, with the majority showing a non–germinal-center immunophenotype according to the Hans algorithm.[43] This most likely reflects origin from a post–germinal center cell, which is blocked from full plasma differentiation.[491,492]

Clinical Course

The poor outcome of IVLBCL in the older literature is related in part to the failure to make a correct antemortem diagnosis.[433] The extended time interval from onset of symptoms to diagnosis significantly contributes to poor outcome in these patients.[473] Combination immunochemotherapy including rituximab has significantly improved the clinical outcome of IVLBCL in both recent Western and Asian series.[493-495] A retrospective study including patients treated before and after the use of rituximab demonstrated that while the majority of patients will die of their lymphoma, there were many other causes of death.[496] CNS recurrence can be detected in up to 18% of cases, even if not initially involved. Inclusion of high-dose methotrexate and intrathecal chemotherapy was recently reported (including patients without evidence of CNS involvement) with a 2-year PFS of 76%.[497,498] Rare cutaneous variant cases with a protracted clinical course have also been reported.[434,499] The hemophagocytic syndrome–associated variant is aggressive and has a median survival of 7 months.[426,491]

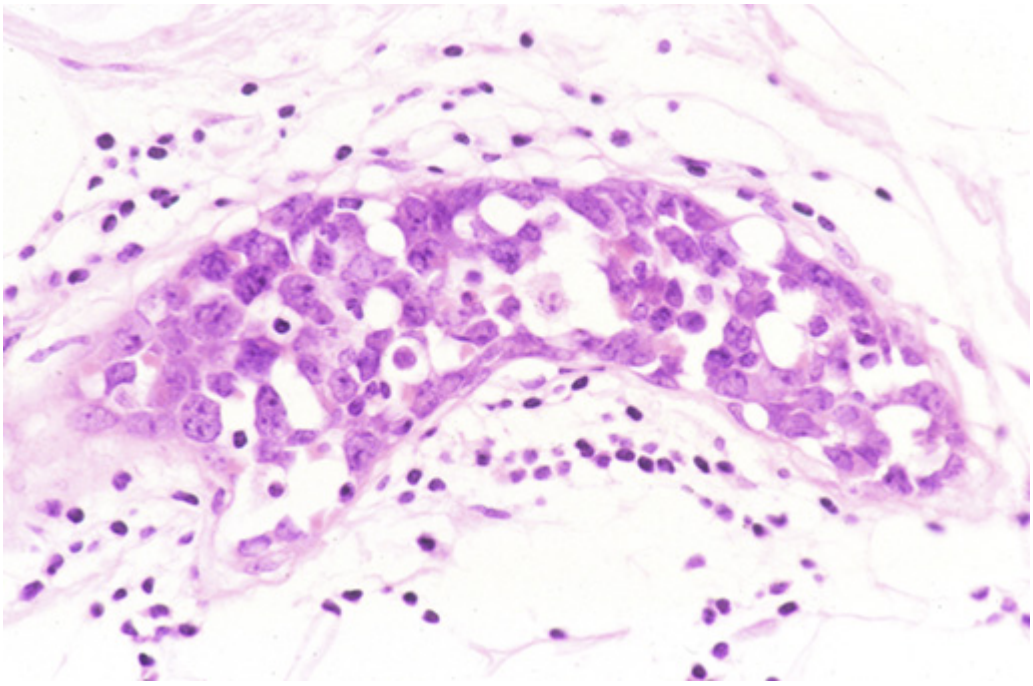

FIGURE 22-36 Intravascular large B-cell lymphoma involving subcutaneous tissue.Palisading of tumor cells along the luminal side of the blood vessel results in an angiosarcoma-like appearance.

Differential Diagnosis

The most difficult part of diagnosing IVLBCL lies in initially including this disease in the differential diagnosis for patients with an extremely wide variety of presentations involving multiple organ systems and then deciding on a location to biopsy when no masses are present. Numerous case reports exist in the literature describing patients with highly unusual presentations in which the diagnosis of IVLBCL was not initially considered. Many patients are only diagnosed at the time of autopsy.[500] Once the possibility of IVLBCL is considered, there are several studies supporting the use of random

skin biopsies of normal-appearing skin (with a preference for incisional over punch biopsies so as to reach the middle adipose tissue) as a first approach to obtaining diagnostic tissue in patients with or without CNS involvement.[501-506] Should skin biopsy be negative, bone marrow biopsy or biopsy of an accessible organ with dysfunction might be considered next. Brain biopsy, in the case of patients with neurologic symptoms, is sometimes the last choice. Recently molecular evaluation for typical IVLBCL gene mutations have been described using cell-free DNA techniques in serum/plasma or cerebrospinal fluid, which may allow for a less invasive diagnosis.[492] Mutated genes investigated in this way for diagnostic use have included *CD79B, PIM1, MYD88, PRDM1,* and *BTG2*.[492,507]

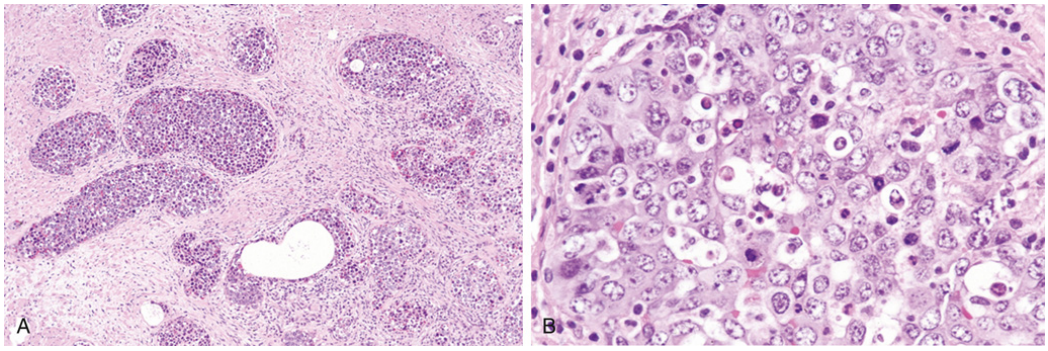

FIGURE 22-37 Intravascular large B-cell lymphoma mimicking carcinoma.**A,** In the prostate, plugging of the blood vessels by tumor cells results in a pattern reminiscent of islands of carcinoma. **B,** This island resembles high-grade carcinoma because of the apparently cohesive growth and the presence of glandlike spaces.

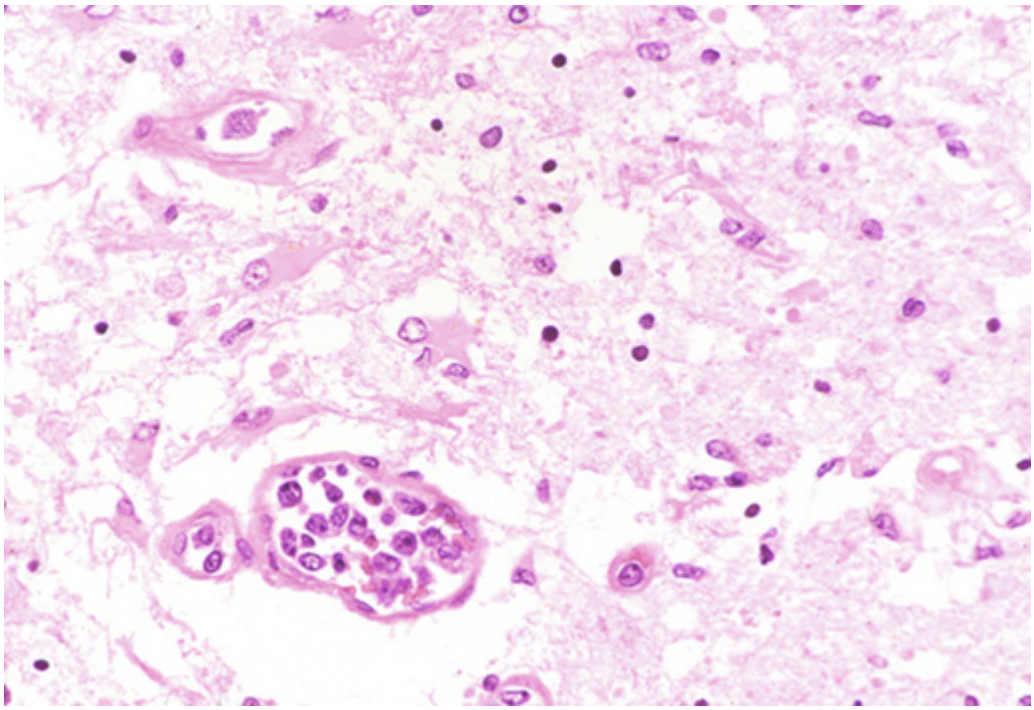

FIGURE 22-38 Intravascular large B-cell lymphoma involving the brain.The blood vessels are filled with large lymphoma cells. The surrounding brain parenchyma shows rarefaction caused by ischemia from the vascular occlusion.

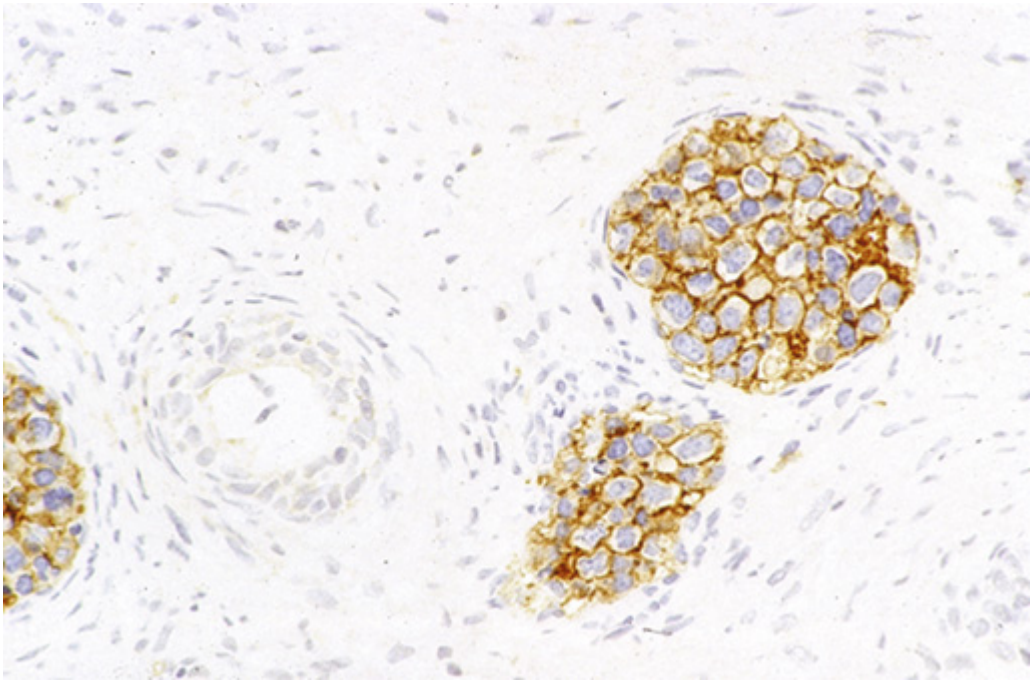

FIGURE 22-39 Immunohistochemistry of intravascular large B-cell lymphoma.The neoplastic cells within the blood vessels are selectively highlighted by CD20 immunostain.

The differential diagnosis with reactive/inflammatory processes can sometimes be confused with IVLBCL when the lumens of the lymphatic channels adjacent to inflamed tissue (e.g., acute appendicitis) are sometimes packed with reactive lymphoid cells.[508] However, these lymphoid cells are smaller, do not have the atypical nuclear features of IVLBCL, and are usually made up of T lymphocytes.

Occasionally, lymphatic spread by a nodal or extranodal large B-cell lymphoma (such as DLBCL, NOS) can be confused with IVLBCL. In this case, clinical features including the overall anatomic pattern of disease and biopsy of any other masses may be helpful.[425] Rare cases of IVLBCL are of T-cell or NK-cell lineage.[509-514] Such cases

often show association with EBV.[509,512-515] Cases with a T-cell phenotype may include intravascular ALK-positive anaplastic large-cell lymphoma or the more indolent intralymphatic primary cutaneous anaplastic large cell lymphoma/lymphomatoid papulosis (CD30-positive lymphoproliferative disorders of skin).[516] Intravascular lymphoma of true histiocytic lineage has also been described.[517,518] None of these cases should be classified as IVLBCL.

In acute leukemia, intravascular collections of blast cells can be seen. The blasts usually have fine chromatin, and cytoplasmic granules may be present in the myeloid type. Blasts in acute myeloid leukemia usually express myeloperoxidase but not pan–B-cell or pan–T-cell markers, whereas those in acute lymphoblastic leukemia express TdT with pan–B-cell or pan–T-cell markers. IVLBCL is always TdT negative.

In patients with carcinomatosis, clusters of carcinoma cells may be lodged in the small lymphovascular channels and initially appear to be IVLBCL. However, the tumor cells are generally cohesive, and they are cytokeratin positive and CD45 negative. Alternatively, “collisions” of incidental IVLBCL with other epithelial and nonepithelial tumors (in which two neoplasms are present) have been described and recently summarized. The low-power appearance of small-to-medium-sized vascular lumens expanded by dyscohesive cells with follow-up immunophenotyping are the key to the diagnosis of IVLBCL.[425]

Pearls and Pitfalls

CHL, Classic Hodgkin lymphoma; *DLBCL, NOS,* diffuse large B-cell lymphoma; *EBV,* Epstein-Barr virus; *HGBL,* high-grade B-cell lymphoma; *PMBL,* primary mediastinal large B-cell lymphoma.

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

- Although a diagnosis of DLBCL, NOS can be suspected by morphology, immunohistochemical confirmation is necessary because many types of lymphoma, leukemia, and non-hematolymphoid neoplasms can mimic DLBCL. In most circumstances, a simple immunohistochemical panel of CD20 and CD3 is sufficient to delineate the lineage.
- Detection of rearrangements of *MYC* and *BCL2* (and *BCL6*) should be performed in all cases, where resources allow, to exclude HGBL-*MYC/BCL2*. This can be done sequentially (testing for other rearrangements only when *MYC* is rearranged) or concurrently, per institutional protocol.
- The cell of origin (germinal-center B-cell type versus activated B-cell/non–germinal-center B-cell type) should be determined, either by molecular or immunohistochemical method (specifying methodology being used).
- In young patients, reactive conditions must be seriously considered in the differential diagnosis. Reactive conditions (in particular infectious mononucleosis) have to be suspected when the large cells show heterogeneous staining for CD20, there are many admixed large T cells, and Waldeyer's ring is involved.
- When bone marrow is involved, it is important to distinguish between involvement by large B-cell lymphoma and small-cell

or follicular lymphoma (discordant lymphoma). The former is associated with a poorer prognosis.

- If DLBCL, NOS is EBV positive, it should be reclassified as EBV-positive DLBCL with investigation into potential causes of underlying immunosuppression (e.g., posttransplant lymphoproliferative disorder, HIV-associated lymphoma, methotrexate-associated lymphoproliferative disorder).
- If DLBCL is suspected but CD20 is negative, consider the possibility of prior rituximab therapy, ALK-positive large B-cell lymphoma, plasmablastic lymphoma, and anaplastic plasmacytoma. Apply additional B-lineage markers such as CD79a, PAX5, CD22, immunoglobulin, OCT-2, and BOB.1.

Primary Mediastinal Large B-Cell Lymphoma

- A superior-anterior mediastinal mass in a young adult woman is most commonly caused by PMBL or nodular sclerosis Hodgkin lymphoma. DLBCL, NOS, mediastinal germ-cell tumor and T-lymphoblastic lymphoma are additional considerations, particularly in young male patients.
- CD30 expression is not helpful in distinguishing nodular sclerosis CHL from PMBL. The histologic features and immunoprofile must be taken into consideration to make the distinction. If the findings are indeterminate (e.g., CD30 positive, CD15 negative, CD20 positive), lack of OCT-2 and BOB.1 staining and positive staining for EBV-LMP1 favor a diagnosis of nodular sclerosis CHL. Cases with intermediate features are categorized as mediastinal gray-zone lymphoma.

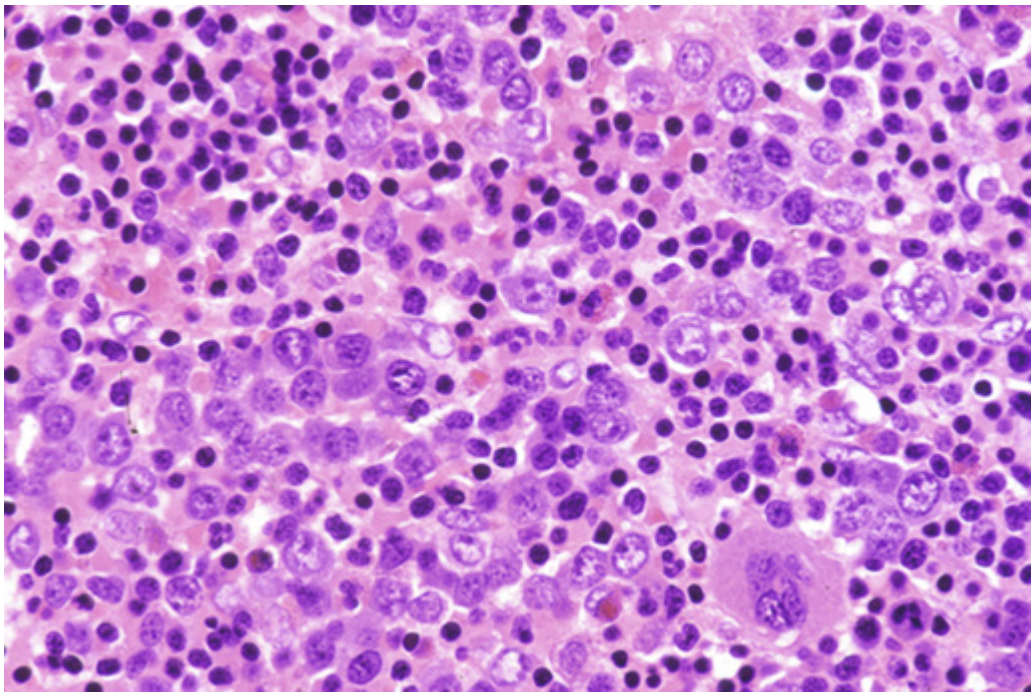

FIGURE 22-27 Extramedullary hematopoietic tumors.The histologic appearance of extramedullary myelopoiesis can lead to a misdiagnosis of diffuse large B-cell lymphoma. Clues to the correct diagnosis include the finding of megakaryocytes *(lower-right field)* and islands of erythroblasts, which can look superficially like lymphocytes *(upper-left field)*. The large cells are, in fact, immature cells of the myeloid and erythroid series.

Why These Four Entities in One Chapter? A Historical Perspective On the Development of Disease Concepts

This chapter combines several distinct entities of mature aggressive B-cell lymphoma: Burkitt lymphoma, high-grade/large B-cell lymphoma with 11q aberration, diffuse large B-cell lymphoma/high-grade B-cell lymphoma with *MYC* and *BCL2* rearrangements, provisional entity diffuse large B-cell lymphoma/high-grade B-cell lymphoma with *MYC* and *BCL6* rearrangements, and high-grade B-cell lymphoma not otherwise specified (NOS). While the entities differ strikingly in their clinical and molecular features, they share overlapping morphology and phenotype. Thus differential diagnosis is a common and challenging task for diagnostic pathologists in their

daily practice. Moreover, these entities are historically linked to each other as they have either not been distinguished from each other in the past or considered more closely related than they are at the present time.

Burkitt lymphoma (BL) is a rather "old" entity, described by Denis Burkitt in 1958 in African children. Soon after the description it was recognized that a disease with identical histopathologic picture also occurred outside Africa but differed in some clinical features. Uncertainty regarding morphologic variability of the disease in elderly patients and the relevance of translocations of the *MYC* gene as possibly the disease-defining alteration led to multiple molecular studies primarily using gene-expression profiling to shape the disease definition and delineate typical BL from other B-cell lymphomas with similar histopathology.[1,2] In these molecular studies, an initially small group of lymphomas were shown to carry a Burkitt signature by gene expression but lacked translocations involving the *MYC* gene. As this group of lymphomas showed considerable morphologic and immunophenotypic similarities with BL, it was initially named *Burkitt-like lymphoma with 11q aberration* in the update of the World Health Organization (WHO) 4th ed. After the genetic landscape of this lymphoma was described and found to be distinct from BL, the name was changed to *large cell* or *high-grade B-cell lymphoma with 11q aberration* in the International Consensus Classification (ICC) and WHO 5th ed., respectively (**Table 23-1**).[3,4]

Diffuse large B-cell lymphoma/high-grade B-cell lymphoma with *MYC* and *BCL2* rearrangements and high-grade B-cell lymphoma, not otherwise specified (NOS) took a similar route of development.

The gene expression studies on BL were mainly intended to define BL molecularly and to provide a better diagnostic distinction from other large B-cell lymphomas especially from diffuse large B-cell lymphoma, NOS (DLBCL, NOS). The gene expression approach used at that time assigned mature aggressive B-cell lymphomas either to the Burkitt group (molecularly defined BL) or to a less well-defined group of lymphomas that were heterogeneous but unified in the fact that they were definitely not BL. The bioinformatic approach of these studies indicated a group of lymphomas that statistically neither fulfilled the criteria of molecularly defined BL nor allowed them to be assigned to the "non-molecular Burkitt" group. The lymphomas of this group were "intermediate" between molecularly defined BL and non-BL in their gene-expression profiles and were enriched for lymphomas with blastoid morphology or synchronous translocations involving *MYC* and *BCL2* or *BCL6*. Soon it became evident that this group of lymphomas differed clinically and molecularly from BL and were subsequently termed *B-cell lymphoma, unclassified, with features intermediate between Burkitt and diffuse large B-cell lymphoma* (used in the WHO 4th ed. in 2008). Subsequently, in the revised WHO 4th ed. in 2017, this category was further subdivided into two groups. The first group, including cases defined by their "intermediate" morphology but lacking specific diagnostic molecular features (except frequent *MYC* translocations), was termed *high-grade B-cell lymphoma, NOS*. Because high-grade B-cell lymphoma, NOS is mainly separated from DLBCL by morphologic features, which can be subjective, this remains a poorly defined entity. Examining the remaining "intermediate" cases, the presence of double-hit (a *MYC* and *BCL2* or *BCL6* rearrangement in the sense of

a rearrangement representing a “hit”) was associated with unfavorable prognosis. Thus in the revised WHO 4th ed., lymphomas with double-hit or triple-hit (presence of all three—*MYC, BLC2,* and *BCL6*—rearrangements in the same lymphoma) were introduced as *high-grade B-cell lymphoma with MYC and BCL2 and/or BCL6 rearrangements* (**Table 23-1**). Within this group, lymphomas with *MYC* and *BCL2* rearrangements represent a molecularly more homogeneous group sharing mutational features for follicular lymphoma (FL). In contrast, lymphomas with *MYC* and *BCL6* translocations are heterogenous with respect to genetic alterations. Moreover, lymphomas with *MYC* and *BCL6* translocations are less well defined by fluorescence in situ hybridization (FISH) because of the fact that *MYC* and *BCL6* may fuse as chromosomal translocations rather than presenting two independent genetic lesions. Thus in the proposal for the WHO 5th ed. published in 2022, the entity *double-/triple-hit* was more strictly defined and named as *diffuse large B-cell lymphoma/high-grade B-cell lymphoma with MYC and BCL2 rearrangements*. Of note, these cases may also harbor a *BCL6* translocation and be triple-hit; however, cases with just *MYC* and *BCL6* translocations are no longer considered double-hit by the WHO 5th ed., but are maintained as a “provisional” entity by the ICC in order to promote further study.[4]

Table 23-1

ICC, International Consensus Classification; *WHO,* World Health Organization.

Recent molecular studies identified lymphomas that were molecularly similar to large B-cell lymphoma with MYC and BCL2

rearrangements but without detectable *MYC* or *BCL2* translocation by conventional diagnostic methods using FISH technology.[5,6] These lymphomas were characterized by a clinically aggressive course and histologically mostly seemed to fall into the category of DLBCL, NOS or high-grade B-cell lymphoma, NOS. It is foreseeable that these "high-grade" molecular signature assays could be technologically incorporated into the daily practice of diagnostic pathology so that "high-grade" B-cell lymphomas will be expanded to also include some lymphomas that had been previously classified as DLBCL by morphology. Conversely, we can speculate that a subset of lymphomas with blastoid morphology currently classified as high-grade B-cell lymphoma, NOS will be identified as DLBCL by future gene expression, genetic, or even machine learning or artificial intelligence-based methods. However, novel methods are unlikely to replace conventional diagnostics based on morphology, immunophenotype, and FISH since these molecular high-grade signatures are also detected in true BL, reflecting features of B-cells from germinal center dark zones. Thus, as technology continues to evolve, so will the classification.

BURKITT LYMPHOMA

Definition

BL is B-cell neoplasm composed of monomorphic, medium-sized cells with basophilic cytoplasm, multiple small and often inconspicuous nucleoli, forming dense cohesive sheets sparse in microenvironment except for prominent tingible body macrophages. The lymphoma is characterized by a mature germinal-center B cell (GCB) phenotype with high proliferation index and genetics

including immunoglobulin (IG) heavy or light chain juxtaposition to the *MYC* gene. See **Table 23-1**.

The eponym honors the contributions of Denis Burkitt for the pioneering work that led to the first description of the clinical features of this tumor in 1958. But it was not only the description of the disease but also the association with a certain geographic distribution that fostered the discovery of the Epstein-Barr virus (EBV) within the lymphoma cells and the development of novel therapies that made Dennis Burkitt's work a masterpiece of medical science.[7,8] Burkitt described the disease as a rapidly growing tumor in the jaws of children residing in the "malarial belt" of equatorial Africa and New Guinea.[9,10] Since the first description, the concept of an inflammation driving lymphomagenesis was born, and only a few years later the EBV was first described in a tumor specimen of a BL.[11] BL remained a further source of inspiration for lymphoma researchers as it became the entity in which *MYC* gene locus was mapped to chromosome 8 as one of the first chromosomal rearrangements detected in lymphoma.[12]

The nomenclature for this lymphoma entity has changed over the years. Terms like *lymphoma, Burkitt type*, and *Burkitt's lymphoma* are not recommended any more, and the previous and current ICC and WHO classifications use the term *Burkitt lymphoma*. It is important to mention that the nomenclature has developed differently over time in leukemic diseases. The French American-British classification of acute leukemia included a category of B-cell acute lymphoblastic leukemia (ALL) with vacuoles in the cytoplasm, also known as L3-morphology.[5,13] Nowadays, it is widely accepted that most cases of acute leukemia with L3-morphology reflect BL in

its leukemic presentation when immunophenotype and genetics are taken into account.

Epidemiology

Three subtypes of BL have been recognized and designated as "endemic," "sporadic," and "immunodeficiency associated."[14] "Endemic" BL refers to the disease originally described by Denis Burkitt in African children in the region characterized by high incidence of malaria, which was long considered to be virtually always EBV positive. However, recent data suggest that not the clinical or geographic context, but rather the presence or absence of EBV in the lymphoma cells, determines the molecular biology of the disease. Moreover, current epidemiologic studies showed that EBV-positive and EBV-negative BLs occur virtually everywhere in the world, even the "endemic" regions in Africa.[3]

The "endemic" BL refers to Denis Burkitt's description of the disease and its distribution as the most common childhood cancer in equatorial Africa and Papua New Guinea. Given the high incidence of this disease in a certain geographic region and characteristic presentation as a tumor for the jaws, the disease was considered "endemic." The high percentage of tumors with EBV in the lymphoma cells and the close association with malaria infection in the same areas seemed to confirm that BL shared features with an infectious "endemic" disease. Current studies confirm a high incidence of BL of 1.09/100,000 in East Africa in children <15 years of age and a close association with the presence/incidence of malaria.[15] However, the age-adjusted incidence of BL in children of the same age in central Europe seems to come close to the incidence

reported for Africa, and BL is the most frequent childhood tumor in central Europe too (**https://www.kinderkrebsregister.de/**). Certainly the incidence of the disease in Africa is underestimated by the registry data[15] since, in countries with a medium-to-low human development index, registration coverage and histopathologic diagnostics of diseases is likely incomplete.[16] Mathematical models in fact suggest a much higher incidence of BL in this region of the world.[16] Moreover, the age composition of populations in Africa and central Europe/Northern America differs strikingly. The United Nations International Children's Emergency Fund estimates Africa's child population will reach 1 billion by the year 2055, making it the largest child population among all continents (**https://data.unicef.org/**) and consequently making BL in pediatric patients a challenge for health care in this region of the world.

The vast majority of BL from Africa are EBV positive, whereas the EBV occurs less frequently in BL in other geographic regions (e.g., central Europe is about 20%).[17] In certain regions of the world such as southeastern Brazil, the EBV-association of BL seems to be intermediate between Africa and central Europe/Northern America.[18] Even within Brazil, the EBV-association of the disease varies regionally.[19] The picture becomes even more complex once age of patients is considered. Although larger age-overarching cohorts of BL tested for EBV of patients residing in African "endemic" regions are missing so far, in "sporadic" BL in central Europe, the EBV-association increases with age.[17,20] The presence of EBV is also associated with mutational features of BL—independent of the geographic region or age of the patient.[17,21] In

immunodeficiency-associated BL, the rate of EBV up to 55% in cohorts of PLWH has been reported.[22]

Regardless of the geographic region, BL rates are 2 to 4 times higher in males than females[23] and the male-to-female ratio is highest at younger ages, generally before puberty. In adults, the male-to-female ratio is nearly equal.[23] The adult and elderly BL cases represent about 1% to 2% of all non-Hodgkin lymphomas in adults or the elderly.[24] The clinical presentation differs between BL occurring in young patients with "endemic" and "sporadic" BL, as "endemic" BL mostly presents as tumors of the face or head (often jaws) whereas "sporadic" BL of the same age group frequently forms masses in the abdomen or involves lymph nodes.[25] In immunodeficiency-associated BL, nodal presentation dominates the clinical picture and bone marrow involvement is frequently detected.[26]

In summary, BL worldwide shares features such as a male predominance in young patients and a high relative incidence among childhood cancers. In a global view, BL differs worldwide in respect to the extent of EBV-association, the anatomic distribution of tumors, and association with other diseases such as malaria infection or immunosuppression. Given this complex picture, the designation of individual cases of BL to the "endemic" or "sporadic" BL subtypes can be problematic. Currently there is no pathologic, clinical, or molecular definition of each of these historical subtypes that would allow identification of "sporadic" BL occurring in "endemic" areas of the world and vice versa.[27] Recent molecular studies indicate that EBV-association is a strong determinant of molecular biology of BL,

such that in the future, BL classification may emphasize EBV status rather than the traditional subtypes.[17,21,28]

Etiology and Pathogenesis

Plasmodium falciparum Malaria and Epstein-Barr Virus Infection in "Endemic" Burkitt Lymphoma

Risk factors of BL have been characterized best for BL falling into the historical category of "endemic" disease and include *Plasmodium falciparum* malaria and EBV infection. Whereas EBV can be detected within the neoplastic cells and proteins encoded by the virus may directly contribute to transformation of B cells, the effect of *P. falciparum* to the pathogenesis of the disease may be more indirect since the parasite is not detectable within the lymphoma cells nor within the tumor tissue. Infection by *P. falciparum* malaria may occur repeatedly and may chronically stimulate B cells and suppress T-cell immunity.[29] The infection activates germinal center reactions and activation-induced cytidine deaminase (AID). The enzyme AID is required for somatic hypermutation and class-switch of the IG genes during the germinal center reaction.[30] Unwanted errors of these physiologic genetic processes contribute to the development of *MYC* translocations.[31] The hypothesis that conditions leading to increased AID activity in germinal centers may favor development of BL seems to be supported by findings in EBV-positive BL that show evidence of antigen selection[32] and AID-typical point mutations, suggesting that they arose from germinal center cells with AID activity.[21]

Understanding the role of EBV in the pathogenesis of BL is challenging. As discussed, the rate of EBV detection in BL varies

greatly by age, geographic region, and immune status. EBV is virtually ubiquitously present in the population at risk and over 90% of children in all regions of the world have long been exposed to EBV infection before the age peak of BL, and most children never suffer from BL. A possible explanation may be found in the age when children are EBV-infected. The infection by EBV usually occurs at less than 1 year in sub-Saharan Africa[33] but later in other areas of the world.[34] Early infection has been associated with a high viral burden in infected children—a condition that potentially increases the risk for transformation of B cells.[33] EBV itself encodes for several proteins that have transforming capacity, but only one, the Epstein-Barr nuclear antigen (EBNA)-1, is consistently detected in EBV-positive BL.[35] EBV also likely plays an important role in the early pathogenesis of BL by providing anti-apoptotic signals to B cells, allowing them to avoid cell death during the occurrence of the *MYC* translocation.[36] Indeed, the presence of EBV in the neoplastic cells is associated with various differences in microRNA and gene expression compared with BL negative for EBV.[37,38]

A Role of Epstein-Barr Virus in "Sporadic" Burkitt Lymphoma?

The factors associated with risk of "sporadic" BL in Europe, Asia, and South/North America are not well understood. EBV is detected in only approximately 20% of "sporadic" BL.[39] However, recent data suggest that EBV may also play a role in the pathogenesis of "sporadic" BL. Children suffering from BL in central Europe show significantly more frequent seropositivity (59%) indicating preceding EBV infection compared with patients with other lymphomas (44%

in the age group 0.5–5.9 years).[40] However, the BL cells themselves harbor EBV by EBV-encoded RNAs (EBER) in situ hybridization at similar frequencies (about 20% in this geographic region).[17,20] Of note, the incidence of EBV-positive BL increases with patient age in central Europe and Japan.[17,41] The mutational features of EBV-positive and EBV-negative BL differ independent of whether these lymphomas are "endemic" or "sporadic."[21,28] Thus, the EBV-positive BL arising in "non-endemic" patients may present a molecular counterpart of the "endemic" BL observed in central Africa.[17,42]

How Is Epstein-Barr Virus–Positivity of Burkitt Lymphoma Defined?

The role of EBV in BL requires assessment of EBV infection of the host detected serologically by antibody titers against EBV proteins and presence of EBV in the lymphoma cells. In "endemic" BL, most patients show both serologic features of a previous infection by EBV and EBV within the lymphoma cells. In "sporadic" BL, patients may not have been exposed to EBV prior to the time when BL manifests and the lymphoma cells are thus negative for the virus. However, most patients in countries outside "endemic" areas of the world have been exposed to EBV long before the onset of the disease and the lymphoma cells may either be negative or positive for EBV. The most sensitive technique for assessing the tumor cells of BL specimen at diagnosis is the in-situ hybridization for EBER and the majority of data on the incidence of EBV association are based on this technique. However, a subset of BL may appear negative in EBER in situ hybridization but nevertheless harbor single cells carrying traces of EBV DNA.[43] As EBV is usually maintained in cells in an episomal

manner, it may be lost to various extents during pathogenesis and become undetectable by EBER in situ hybridization.[43] The role of EBV in the pathogenesis of BL may thus be a “hit-and-run” mechanism—a hypothesis that supports the relevance of EBV in early pathogenesis of the disease. Interestingly, this observation also allows the conclusion that EBV may be less relevant for the maintenance of the fully neoplastic clone and its expansion. Using EBER in situ hybridization, EBV is found in most of the lymphoma cells. Subclones lacking EBV have not been reported in BL yet and in most cases the occurrence of EBER-negative cells within an otherwise EBR-positive BL may be best explained by technical artifacts such as by poor tissue preservation.

Immunodeficiency

Persons living with HIV (PLWH) show a high incidence of BL. A survey in the United States between 1980 and 2005 showed a crude incidence of 22.0/100,000.[44] Interestingly, the risk of BL is higher in PLWH with CD4 cell counts above, rather than below, the level defining AIDS and BL is frequently the first presentation of HIV infection.[44] These data suggest that an intact CD4 immune response is required for the pathogenesis of BL (e.g., by supporting germinal center reactions rather than an “immune-escape” of EBV-infected cells). This hypothesis is further supported by the fact that introduction of combined antiretroviral therapy has had little effect on the incidence of BL.[45] Similar findings have been reported for Hodgkin lymphoma. In contrast, the incidence of DLBCL has declined under combined antiretroviral therapy.[46] BL in PLWH is positive for EBV in an age-dependent manner, showing the highest

rates of positivity of 55% in age group 20 to 34 years and with a significant higher positivity rate in Blacks/Hispanics.[22] In addition to HIV, other types of immunodeficiency are associated with an increased risk for BL. For example, after solid organ transplantation, BL is frequently EBV positive and presents as aggressive disease.[47]

Hereditary Burkitt Lymphoma

The high male-to-female ratio in younger patients suggests a genetic basis for susceptibility in BL.[48] Moreover, rare cases of familial BL have been reported, including families with germline variants in *TCF4* and *CHD8*.[49] In addition, rare inherited disorders have been associated with increased risk of BL, including Purtillo/Duncan Syndrome/XLP (OMIM: 308240), XMEN disease (OMIM: 300853), ataxia telangiectasia (OMIM: 615919), and Williams-Beuren Syndrome (WBS; OMIM: 194050).

Clinical Features and Staging

BL frequently presents at extranodal sites, but the localization of these tumors differs between historical subtypes. In “endemic” BL, the facial bones, especially the jaws, are often involved,[50] but more recently, abdominal masses have been described more frequently[51]—a pattern that is otherwise typical for “sporadic” BL. The latter subtype occurs as an abdominal mass mostly in the ileocecal region. In this region, the tumor forms transmural masses of the intestinal wall but mostly spares lymph nodes even when they are localized immediately adjacent to the tumor (**Fig. 23-1**). Other sites frequently involved are the orbit, Waldeyer’s ring, gingiva, thyroid gland, ovaries, and testis.[52-54] Involvement of the breast seems to be rather uncommon but may rarely occur in lactating women.[55] The

clinical presentation of immunodeficiency-associated BL seems to be more heterogeneous with more nodal involvement and combinations of extranodal and nodal presentation.[56] Involvement of the central nervous system (CNS) is rather frequent in BL of all subtypes compared with other mature aggressive B-cell lymphomas. The frequency of CNS involvement differs between reports from population-based[25] and clinical studies from Malawi[57] for "endemic" BL. Data for "sporadic" BL in pediatric patients in the United States and Germany suggest a frequency of CNS involvement between 9% for pediatric[58] and 30% for adult BL.[59]

The clinical picture of patients suffering from BL is characterized by fast-growing masses because of the short doubling time of BL cells. Thus most patients have a high tumor burden and widely disseminated disease at initial presentation. Systemic symptoms are related to the high tumor cell turnover in a subset of patients. Most symptoms are site-specific and reflect organ dysfunction caused by masses, pain, obstruction, or bone destruction. A leukemic presentation occurs in a variable proportion of patients and is formally defined as >25% blasts in the bone marrow independent of the presence of tissue masses and may be associated with spontaneous tumor lysis syndrome. Leukemic presentation seems rarer in "endemic" BL compared with the immunodeficiency-associated BL (~61%)[60] and "sporadic" BL (~26% in pediatric patients).[54] However, bone marrow involvement may be underestimated in limited resource settings. Because of the frequent presentation of BL in extranodal sites, the Ann Arbor staging system is suboptimal to assess tumor dissemination. Therefore, a revised

staging according to Murphy is commonly used for children, the group of patients in which the disease is most frequent.[61]

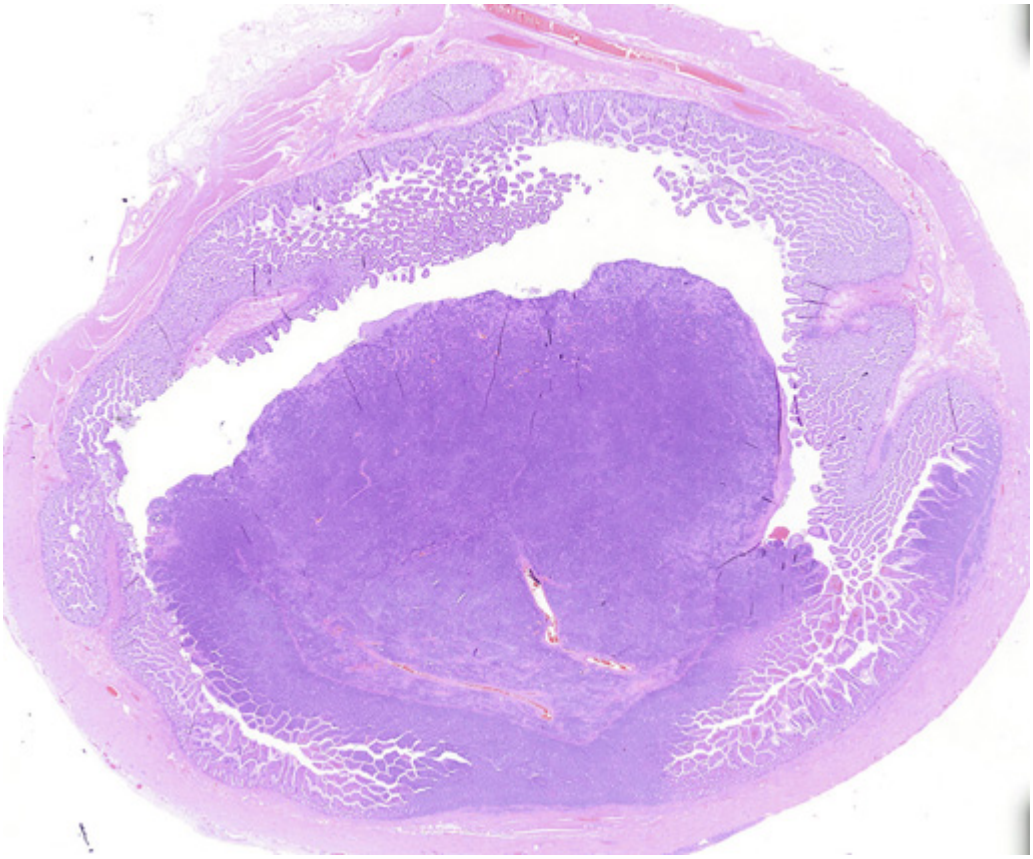

FIGURE 23-1 Burkitt lymphoma forming an abdominal mass in the small intestine and obstruction of the lumen (H&E).

Morphology

BL infiltration of affected tissue is virtually always obvious and partial infiltration (e.g., of lymph nodes) is rare. The lymphoma grows diffusely, although there are rare cases with a follicular-appearing pattern. Tumor cells are so densely packed that the narrow rim of cytoplasm appears angular, giving the low-power

impression of cohesive growth (**Fig. 23-2**). Scattered macrophages containing apoptotic debris (tingible-body–type macrophages) produce the so-called starry-sky pattern, in which the dense cohesive sheets of blasts appear as the dark sky and the macrophages with bright cytoplasm as the stars (**Fig. 23-2**).

It is important to keep in mind that the starry-sky picture can be lost because of suboptimal tissue quality (late fixation, early necrosis). A subset of cases can display a true granulomatous reaction and this phenomenon has been linked to good prognosis and even spontaneous remissions in single case reports.[62,63] Reactive T-cells are infrequent. Despite the high proliferation, coagulative necrosis is surprisingly rare. The neoplastic cells show round nuclei with clumped chromatin. The nucleoli are small and often paracentrally located (**Fig. 23-3**). Overall, there is little cytologic variability, and the vast majority of BL are quite homogenous in their histologic appearance. However, morphologic variability such as more prominent nucleoli or plasmacytoid differentiation with more basophilic cytoplasm may be observed, especially in immunocompromised patients.

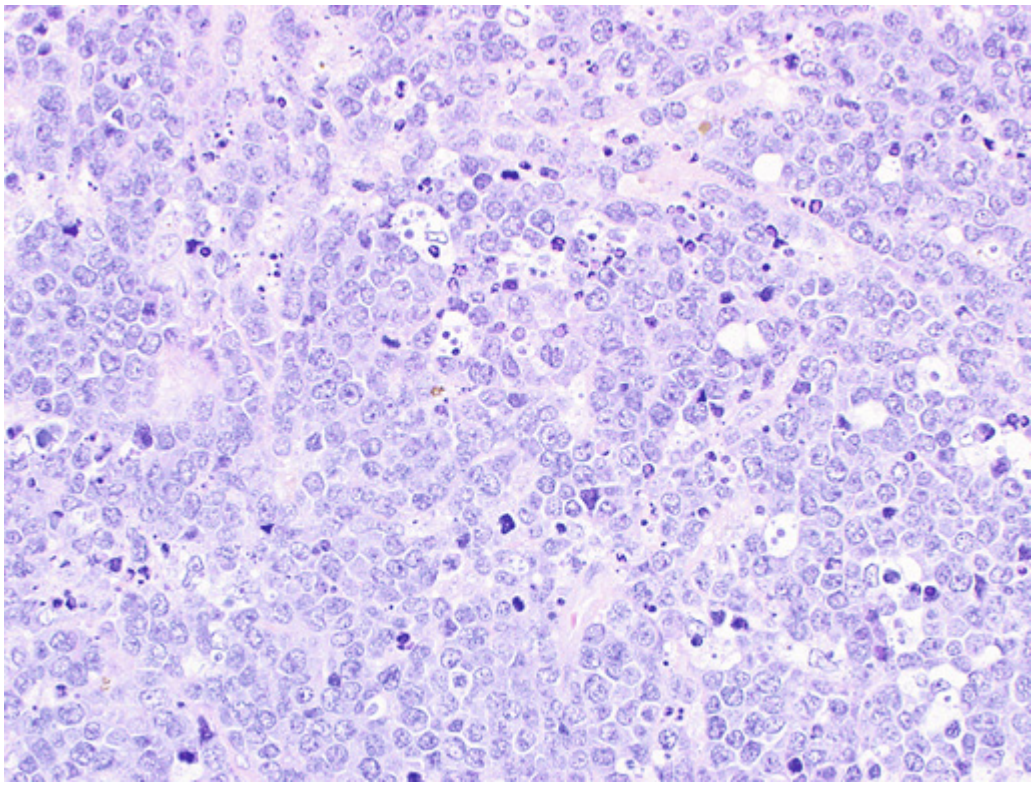

FIGURE 23-2 Burkitt lymphoma with starry-sky appearance (H&E).

In cytologic preparations, such as imprints and smears, the morphology differs because the dense packing of the cells is lost during preparation. The medium-sized lymphoid cells have deeply basophilic roundish cytoplasm that shows lipid vacuoles (designated as L3 morphology in historical classifications,[13] **Fig. 23-4**). The nuclei appear as round as in histology slides and show multiple basophilic small nucleoli.[64-66] **Box 23-1** summarizes the diagnostic features of BL.

Immunophenotype

The immunophenotype of BL is characterized as a mature B-cell phenotype with germinal center markers, absent or weak *BCL2,* and

a very high Ki67. BL shows a mature lymphoid phenotype and is thus virtually always terminal deoxynucleotidyl transferase (TdT) negative (**Fig. 23-5**). BL is characterized by expression of B-cell antigens found in mature B cells (CD19, CD20, CD79a, CD22, and PAX5). Lack of one of these markers is uncommon at initial diagnosis (before treatment). In daily practice, CD20 is often the marker of choice (**Fig. 23-5**). Immunoglobulin (Ig) M is usually positive on BL cells but immunohistochemistry for IgM is prone to staining artifacts. BL expresses germinal center markers such as CD10, BCL6, CD38, HGAL, GCET1, and MEF2B, of which strong and abundant expression of CD10 seems to be the most helpful (**Fig. 23-5**). CD10-negative BLs are exceedingly rare, if they exist at all. Expression of markers that are often considered T-cell antigens such as CD43, TCL1, and LEF1 may be found in BL,[67-70] but truly lineage-specific T-cell antigens such as CD3 are absent. MYC expression by immunohistochemistry is high (usually >80% of tumor cells). Rarely, BL lacks positivity for MYC by immunohistochemistry because of mutations and alternative mechanisms of MYC regulation.[71,72] It should be noted that MYC immunohistochemistry requires optimal fixation and tissue processing, and interpretation of MYC staining results needs to be scored in well-preserved areas of the tissue only. Immunohistochemistry may replace FISH for *MYC* in a resource limited setting. However, the gold standard to detect MYC rearrangements, as a part of the diagnostic criteria, would still be the detection of the translocation by cytogenetics, FISH, or any other molecular technique. The high proliferation of BL is reflected by a Ki-67 expression in typically >95% of neoplastic cells (**Fig. 23-5**). In fact, in well-preserved tissue areas, virtually only non-neoplastic cells

(macrophages, T cells) will be Ki67-negative upon close examination. Therefore, it is recommended to assess the Ki67 staining in well-preserved areas at a high magnification. Absence of BCL2 staining is a characteristic feature of BL (**Fig. 23-5**). If BCL2 is positive, it is usually only weakly expressed and appears weaker than the reactive T cells in the same tissue specimen (**Fig. 23-5**).[73]

Box 23-1 Diagnostic Criteria for Burkitt Lymphoma

Key Features

Medium-sized, monomorphic lymphoma cells with basophilic cytoplasm and multiple small nucleoli

CD20 and CD10 positivity; absence or weak expression of *BCL2*; Ki67 index >95%

High expression of MYC (>80%) or demonstration of MYC breakage or *IG*::MYC translocation

Additional

Starry-sky pattern, "cohesive" growth pattern

BCL6 positivity, terminal deoxynucleotidyl transferase (TdT) negativity, CD38 positivity

Absence of *BCL2* and *BCL6* translocations (mainly required in adult patients)

Flow Cytometry

Flow cytometric analysis of BL tumor cells usually shows a low expression of CD45, but abundant B-cell markers and CD10. Bright expression of CD38 is a typical feature of BL and more often used in diagnostic algorithms of flow cytometry compared with immunohistochemistry. Also, by flow cytometry, BL cells lack expression of BCL2, CD44, and TdT.[74-76]

Genetics/Molecular Findings

Immunoglobulin Genes

The immunoglobulin (IG) genes of BL cells are clonally rearranged. The breakpoints within the IG genes vary between historical subtypes of BL (**Table 23-2**) and may be associated with outcome.[77] In addition, the intact allele that is not involved in the *IG::MYC* translocation shows evidence of activity of AID as detected by somatic hypermutations. Interestingly, the level of somatic

hypermutation in the IG genes is higher in EBV-positive compared with EBV-negative BL,[21,32] suggesting that a pathogen-driven, germinal center-activating and AID-dependent role is more prominent in EBV-positive BL compared with EBV-negative BL.

Table 23-2

BL, Burkitt lymphoma; *EBV,* Epstein-Barr virus; *PLWH,* patients living with HIV.

* Latest data suggest interdependence of EBV and localization of IGH breakpoints.[42]

MYC Translocations

The molecular genetic hallmark of BL is a translocation juxtaposing the *MYC* oncogene on 8q24 next to one IG loci, which is the IG heavy chain locus [*IGH*::*MYC,* t(8;14)(q24;q32)] in most cases followed by the kappa [*IGK*::*MYC,* t(8;22)(q24;q11)] and the lambda [*IGL*::*MYC,* t(2;8)(p12;q24)] light chains.[78] The localization of the breakpoints in the IG genes suggest that they result from AID-mediated somatic hypermutations or class-switch recombinations of the IG genes and AID-induced mutations or breakpoints in *MYC*.[42,79] The *IGH*::*MYC* and variants lead to juxtaposition of the intact *MYC* gene to IG enhancers, resulting in constitutive expression of *MYC,* compared with the dynamic expression in normal GCB, where it is restricted to a limited number of cells and short periods of time.[80,81] *MYC* encodes a transcription factor that has multiple, complex, and cell context-dependent functions (e.g., MYC is considered to be an amplifier of gene expression, meaning that MYC promotes expression of many genes that are specifically transcribed in a

particular cell).[82] In the pathogenesis of BL, the *IGH::MYC* translocation and consequent MYC overexpression is assumed to first occur in a germinal center B cell. Several potential functions of MYC during pathogenesis can be envisioned, such as (1) enhancement of apoptosis, proliferation, metabolism, and angiogenesis; (2) alteration of apoptosis; and (3) genesis of DNA damage and the disruption of double-stranded DNA repair, potentially leading to increased chromosomal abnormalities (**Fig. 23-6**).[83]

The position of the *MYC* breakpoints depends on the IG partner gene. In the case of t(8;14) involving the IG heavy chain, breakpoints typically lie within the centromeric (5′) part of the *MYC* locus. However, structural differences exist between the three epidemiologic subsets of BL: In "sporadic" and immunodeficiency-associated BL, most breakpoints are nearby or within *MYC,* whereas in endemic cases, most breakpoints are dispersed over several hundred kilobases further upstream of (centromeric to) the gene (**Box 23-1**).[84-86] This variable distribution may explain why breakpoints are missed in some break-apart FISH assays. In endemic BL, the breakpoints in the IGH locus at 14q32 usually occur 5′ of the intron enhancer in a joining (J) or diversity (D) segment; but in "sporadic" and HIV-associated BL, they mostly occur within or nearby one of the switch regions (**Box 23-1**).[84-86] Of note, recently cases with cryptic insertion of *MYC* into the IGH locus have been reported. These cases, and lymphomas with widely dispersed *MYC* breakpoints, may escape detection by FISH.[87] Of note, when the partner is IGL or IGK, the breaks in the *MYC* locus are typically downstream of (telomeric to) the *MYC* gene[88] and this genetic

constellation has been reported to be associated with unfavorable prognosis in advanced-stage pediatric BL.[77]

Other Mutations and Pathways in Burkitt Lymphoma

Translocations involving *MYC* and the IG genes are considered primary oncogenic events in BL. They usually are part of a simple karyotype, which means that no or very few additional chromosomal aberrations are detectable.[89] The most common secondary aberrations (occurring in 44% of cases) are copy number gains involving 1q, 7, and 12 and losses involving 6q, 13q32-34, and 17p. Gain of 1q seems to be associated with a lack of other recurrent abnormalities. Interestingly, in cases of BL that relapse after therapy, a condition associated with poor outcome, an increase of chromosomal complexity has been observed.[90] The low frequency of chromosomal imbalances identified by conventional cytogenetic studies was confirmed by molecular studies using array comparative genomic hybridization[91] and whole genome sequencing.[92] Chromosomal gains and losses show an identical pattern in pediatric and adult typical BL,[93,94] albeit the mutational profile differs with age and EBV status.

BL harbors mutations in genes that control cell proliferation, growth, and survival, but none of these molecular genetic alterations is as consistently found as the *IG::MYC* translocations. The most frequently mutated genes are the transcription factor *TCF3* (previously called E2A) or its repressor *ID3,* which supposedly result in tonic activation of B-cell receptor (BCR) signaling.[95-97] Another gene frequently mutated in BL is *CCND3,* which shows activating mutations often in combination with loss of function mutation of its

inhibitor *CDKN2A*. These mutations are thought to promote G_1-S phase transition and contribute to the very short cell cycle with a 24-hour doubling time characteristic for BL. Other recurrent mutations in BL affect *MYC* itself, *TP53, GNA13,* and *SMARCA4*. Pathways that are commonly affected by mutations are BCR and PI3K signaling, apoptosis, SWI/SNF complex, and G-protein coupled receptor signaling.[92,98]

Recently the frequency of these mutations in BL was shown to be dependent on the EBV status of the lymphoma cells (EBER positive versus negative). Presence of EBV and mutations in *TCF3/ID3* were virtually exclusive in these studies, suggesting that these somatic mutations and EBV may have similar functions during lymphomagenesis.[17,21,28] Thus, a dual mechanism of BL pathogenesis—mutational versus viral driven—has been suggested[17,21,28] and may replace the historical subtyping of BL in the future.[42,99]

Postulated Cell of Origin

Germinal center B cell.

Clinical Course

The prognosis of BL treated with optimized immunochemotherapy, including anti-CD20 antibodies, is generally excellent with event-free survival reaching 90% in children[100,101] and 75% in adults.[102] A BL International Prognostic Index is used to assign patients to a low-risk, intermediate-risk, or high-risk group with overall survival rates of 96%, 76%, and 59%, respectively.[79,103-105] The outcome of patients with “endemic” BL is less good and depends on the

resources for diagnosis and treatment,[51,106] but has improved with the introduction of polychemotherapy developed for “sporadic” BL.[107] Thus, it seems reasonable to assume that “endemic” and “sporadic” BL do not differ in outcome because of the aggressiveness of the disease but rather because of the health care provided to patients. Additionally, patient outcomes from EBV-positive BL occurring in a “sporadic” setting do not differ from EBV-negative lymphomas when treated similarly.[20] Involvement of the CNS is a risk factor for relapse.[58,108] Once BL relapses after first-line therapy, the outcome is dramatically worse compared with the initial diagnosis,[109,110] but salvage therapy can also be effective.[59,110]

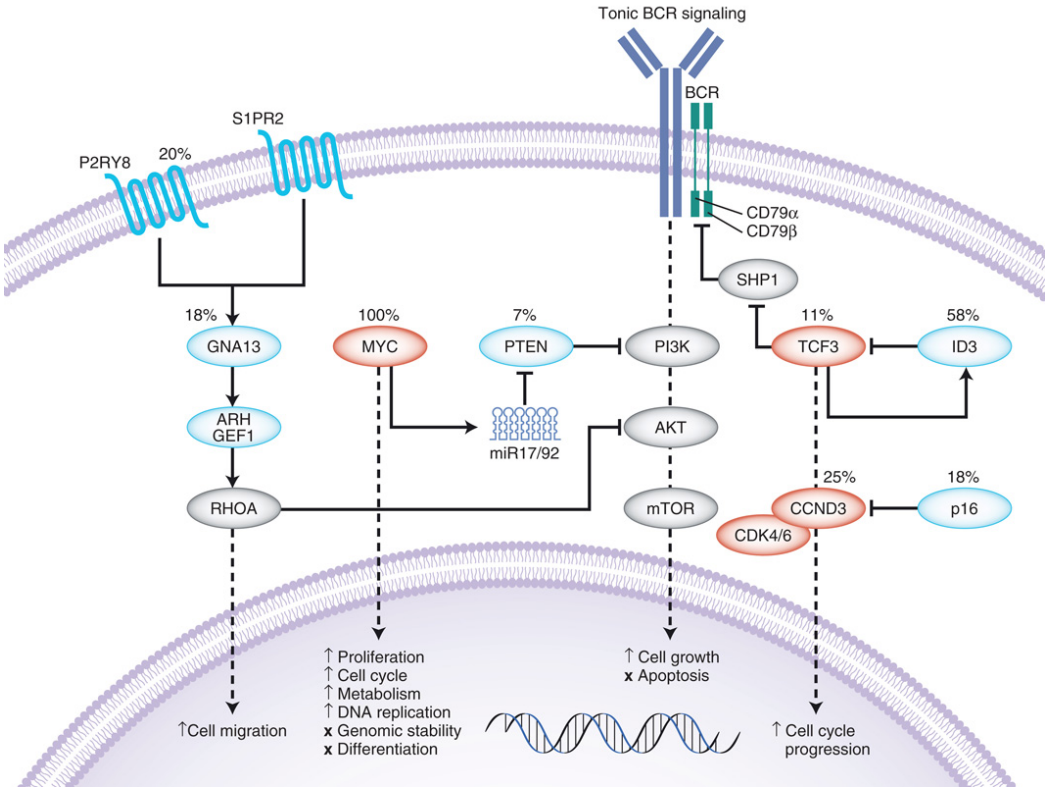

FIGURE 23-6 Pathogenetic pathways and mutations in Burkitt lymphoma. Modified from Fangazio M, Pasqualucci L, Dalla-Favera R. Chromosomal translocations in B cell lymphoma. In: Rowley JD, et al, eds. Chromosomal Translocations and Genome Rearrangements in Cancer. Switzerland: Springer International Publishing; 2015.

Differential Diagnosis

Most BL can be diagnosed by morphology and a limited number of immunohistochemical stains with sufficient certainty. The differential diagnosis of BL is principally the same in all patients (**Table 23-3**). However, the clinical context can guide the selection

of diagnostic testing. Since BL is the most frequent neoplasia in children and adolescents but rare in adults, the diagnostic strategy in adult patients may be oriented toward diagnoses more common in this age group. In children, the differential diagnosis should include careful exclusion of precursor B-cell lymphomas/leukemias. For countries with limited resources for laboratory testing, simplified diagnostic criteria have been proposed.[111]

The immunophenotype of BL is particularly consistent and should be CD20 positive, CD10 positive, BCL2 negative or partial and weak, and KI67 >90%. In children it may be wise to exclude a precursor B-cell lymphoma by demonstrating absence of TdT. Confirmation of the diagnosis is optimally achieved by demonstrating *IG*::*MYC* translocation juxtaposing MYC to either the IGH locus by t(8;14)(q24;q32) (80% of the cases) or, less commonly, to the IGL or the IGK locus by t(8;22)(q24;q11) and t(2;8)(p12;q24) translocations by FISH or cytogenetics. However, in cases with typical morphology and immunophenotype, the use of a break-apart probe for *MYC* is commonly accepted to prove the diagnosis. In adults and any cases with morphologic or immunophenotypical deviation from the expected, breaks in *BCL2* and *BCL6* should be excluded and *IG*::*MYC* should be demonstrated to achieve a high specificity of diagnosis. Whether a *BCL6*::*MYC* translocation can substitute for an *IG*::*MYC* translocation is currently uncertain. *MYC* translocations partnering with other non-IG genes are not typical for BL and should warrant further testing to exclude DLBCL.[7] Similarly, a complex karyotype or multiple chromosomal imbalances are uncommon in BL at first presentation and may lead to additional testing. Of note, mature aggressive B-cell lymphomas with a typical phenotype of BL

(CD20 positive, CD10 positive, BCL6 positive, BCL2 negative, Ki67>95%), an *IG*::*MYC*, and no *BCL2* or *BCL6* translocation, are similar to BL in their mutational pattern even if their morphology deviates from typical cases of BL.[112]

Table 23-3

BL, Burkitt lymphoma; *DLBCL,* diffuse large B-cell lymphoma; *NOS,* not otherwise specified; *TdT,* terminal deoxynucleotidyl transferase.

* Region of loss is the terminal end of the long arm of chromosome 11.

Although genetic testing for *MYC* is the gold standard to confirm the diagnosis of BL, there are certainly limitations of this concept. First, conventional cytogenetic or molecular methods may miss some *IG*::*MYC* translocations[9] and biologically equivalent alterations leading to MYC deregulation such as cryptic insertions of *MYC* into IGH.[8] However, testing for these alterations depends on sequencing technology, which is currently not available for routine diagnostic testing. Testing for recurrent mutations in BL may guide the diagnosis but its value has not yet been demonstrated for clinical decision making. Second, genetic analyses such as FISH studies on FFPE sections or cytologic smears are currently not available in all parts of the world. To address this, an alternative algorithm for the diagnosis of BL has been proposed that includes immunohistochemistry for MYC instead of testing for *MYC* translocations.[111]

LARGE/HIGH-GRADE B-CELL LYMPHOMA WITH 11Q ABERRATION

Definition

Large/high-grade B-cell lymphoma with 11q aberration (L/HGBL-11q), formerly known as a *Burkitt-like lymphoma with 11q aberration*, is a mature aggressive B-cell lymphoma with a characteristic chromosome 11q-gain/loss pattern often morphologically and immunophenotypically similar to BL. See **Table 23-1** with synonyms and related terms and **Box 23-2** for diagnostic criteria.

Epidemiology

Systematic analyses of the incidence of L/HGBL-11q have not been published yet; however, the entity is likely rare. Most cases reported so far have been diagnosed in children/adolescents and patients under the age of 60 years.[113-116]

Etiology and Pathogenesis

The etiology of L/HGBL-11q is unknown. Despite morphologic and clinical similarity to BL, a geographic distribution like BL has not been documented yet. Given the fact that L/HGBL-11q resembles BL morphologically and immunophenotypically and may only be identified by genetic testing for *MYC* and 11q aberrations, this entity might frequently be missed diagnostically, and its incidence underestimated.

Box 23-2 Diagnostic Criteria for L/HGBL-11q

Key Features

Characteristic intermediate/blastoid or Burkitt-like morphology in concert with the typical immunophenotype (CD10 positive, BCL6 positive, BCL2 negative)

Chromosome 11q-gain/loss, telomeric loss or telomeric loss of heterozygosity pattern

Absence of a MYC translocation

Additional

Expression of CD56 in the absence of $CD38^{high}$ by flow cytometry

Clinical Features

Most patients present with symptoms related to the tumor masses. Generalized symptoms like B-symptoms seem to be rare.[113-115] Immunocompromised patients have been reported to suffer from L/HGBL-11q.[117] In pediatric patients, an association with immunodeficiency has not been established.[113] Staging is performed similar to BL in pediatric patients.[61] Based on the limited data available, the outcome seems to be favorable in pediatric patients treated according to BL protocols, with almost no relapses reported so far.[113,114] The clinical experience with adult patients is more limited. However, patients treated according to protocols developed for adult DLBCL may relapse.[114,115,118]

Morphology

A characteristic feature of L/HGBL-11q is the morphologic and immunophenotypical similarity to BL. Most cases show dense diffuse sheets of cells and a starry-sky pattern with strikingly coarse

apoptotic debris within starry-sky macrophages.[119] The neoplastic cells are medium-sized with chromatin similar to that observed for BL. Variation in nuclear size and nucleoli can be seen (**Fig. 23-7**).[116] However, this may not be a distinguishing feature since BL also shows some morphologic variation. Cases with a pure morphology of DLBCL have been observed, prompting the ICC to choose the term *large B-cell lymphoma with 11q aberration* for this entity.[4] The typical "L3-morphology" in smears/imprints as described for BL is not observed.

Immunophenotype

L/HGBL-11q are mature aggressive B-cell lymphomas (TdT negative) that express abundant B-cell markers such as CD20, CD19, and CD79a (**Fig. 23-8**). In fact, cases lacking expression of CD20 at initial diagnosis have not been observed to the best of our knowledge. The other characteristic features of BL are observed in this entity too: expression of CD10, KI67>90%, and no or only partial or weak positivity for BCL2 (**Fig. 23-9**).[116] Of note, in flow cytometry distinguishing features have been described as expression of CD16, CD56, and CD8, and lack of CD38-high but lineage-specific myeloid or T-cell antigens are not detected.[118]

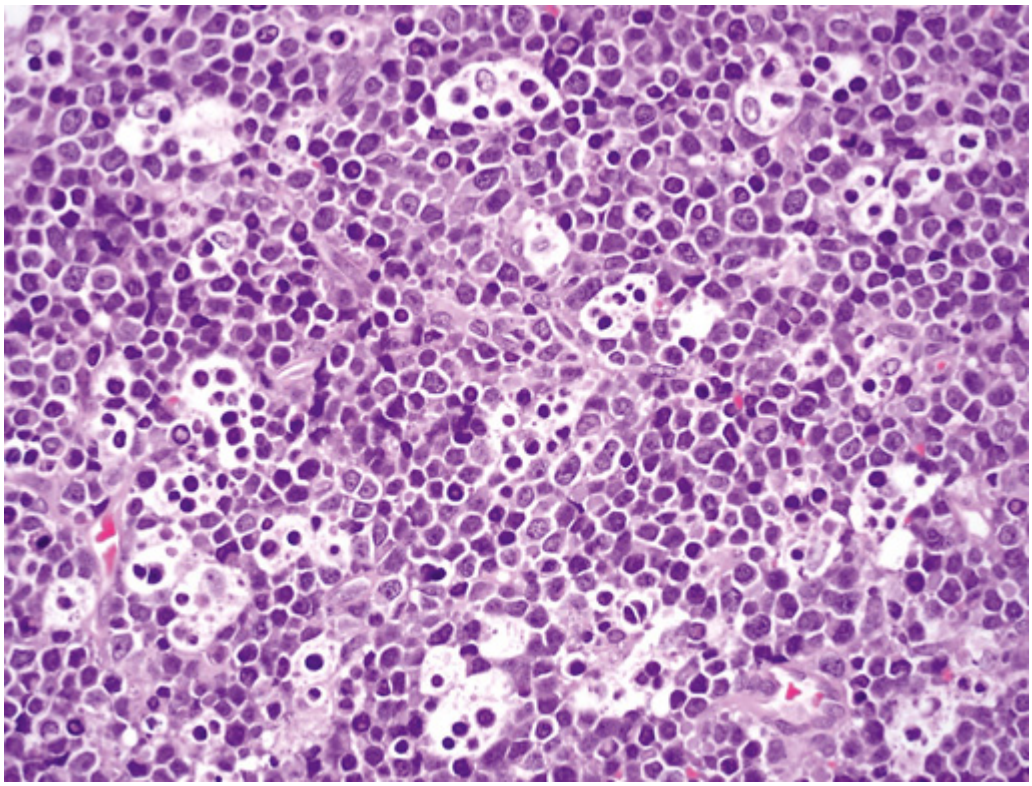

FIGURE 23-7 Morphology of large/high-grade B-cell lymphoma with 11q aberration (H&E).

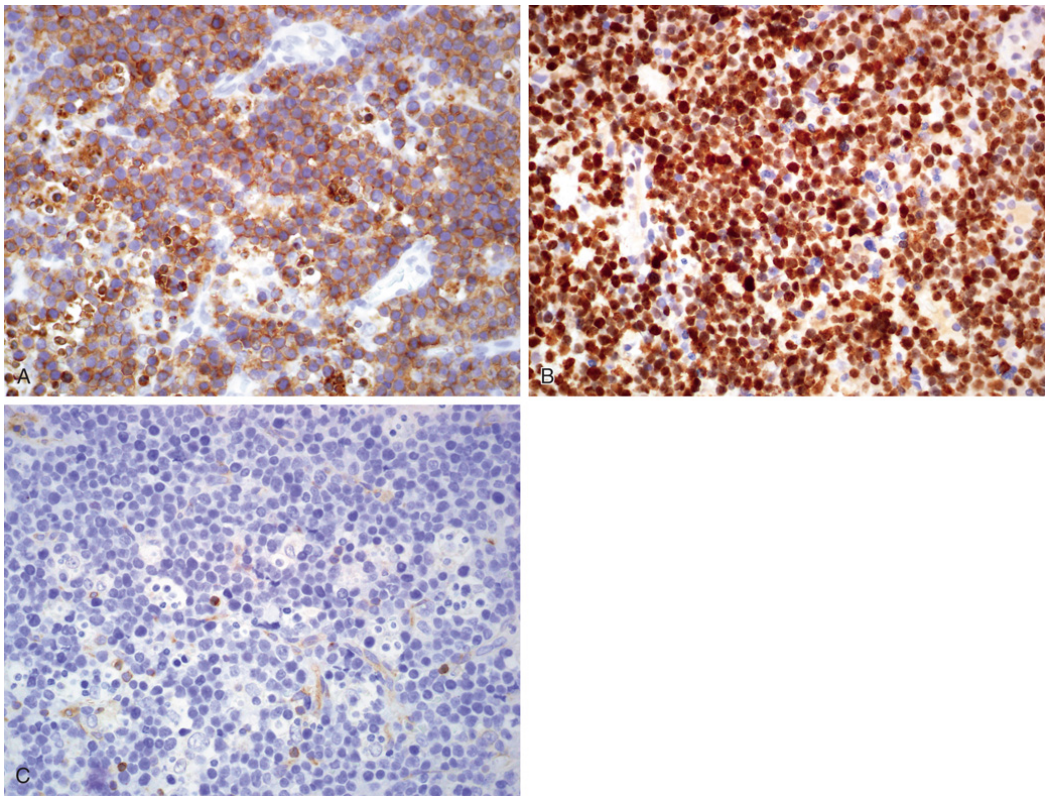

FIGURE 23-8 Immunophenotype of large/high-grade B-cell lymphoma with 11q aberration with expression of CD10 **(A)**, high Ki67 **(B)**, and absence or weak BCL2 **(C)**.

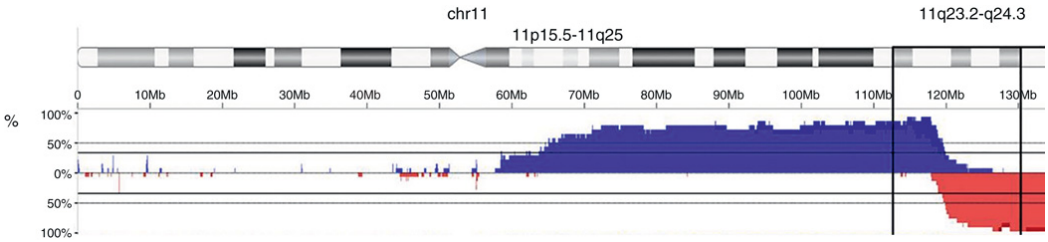

FIGURE 23-9 Chromosomal 11q-gain/loss pattern of large/high-grade B-cell lymphoma with 11q aberration. Modified from Itziar S, Martin-Guerrero I, Wagener R, et al. for the Molecular Mechanisms in Malignant Lymphoma Network Project and Berlin-Frankfurt-Münster Non-Hodgkin Lymphoma Group. A recurrent 11q aberration pattern characterizes a subset of MYC-negative high-grade B-cell lymphomas resembling Burkitt lymphoma. Blood. 2014;123(8):1187-1198.

Genetics/Molecular Findings

Gene-expression profiling shows similarities between BL and L/HGBL-11q,[116] probably reflecting the cell of origin or the frozen state of differentiation of the neoplastic cells—a feature which can, to some extent, be captured by morphology and phenotype. Despite the morphologic similarity, the molecular genetic pathways affected in L/HGBL-11q seem to differ strikingly from BL. In L/HGBL-11q, *MYC* translocations are absent. Genes recurrently mutated in BL, such as those in the ID3-TCF3 pathway, are rarely affected in L/HGBL-11q. However, mutations in other genes such as *KMT2D, SWI/SNF, CREBBP,* and *GNA13,* which are commonly found in DLBCL, have

been detected in L/HGBL-11q.[114,120] The characteristic genetic feature of this lymphoma is a complex aberration involving chromosome 11 (11q) with a minimal region of gain in 11q23.3 and a minimal region of loss at 11q24.1-qter.[116] Some cases solely harbor the telomeric loss, but without the centromeric gain, and may show combinations with a loss of heterozygosity (**Fig. 23-9**).[116] To what extent and how the genetic lesion on 11q contributes to the pathogenesis is still uncertain. Of note, L/HGBL-11q does not harbor EBV virus and thus a role for EBV in the pathogenesis is unlikely. Diagnostic criteria are listed in **Box 23-2**.

Postulated Cell of Origin

Germinal center B cell.

Differential Diagnosis

Since morphology and immunophenotype are not sufficient to distinguish BL from L/HGBL-11q, cases with the morphology and immunophenotype of BL need to be tested for *MYC* translocations. In the absence of *MYC* translocations, testing for the typical gain/loss pattern on 11q is required to confirm the diagnosis of L/HGBL-11q. Testing for MYC expression may be applied when FISH for *MYC* is not available. However, this testing strategy requires a MYC immunohistochemistry protocol and scoring that allows distinction of *MYC* translocation positive and negative lymphomas with sufficient certainty, which can be challenging. In adults, FISH testing for *BCL2* and *BCL6* translocations may be advisable because these do not usually occur in L/HGBL-11q and indicate DLBCL.[116]

The question of how to detect the typical aberration on 11q is a matter of what technology is available. Next-generation sequencing or high-resolution array-based comparative genomic hybridization are certainly the most reliable techniques to identify 11q aberrations because they also detect copy number-balanced lesions (telomeric loss or solely telomeric loss of heterozygosity [LOH] in the absence of gains).[116] However, most labs used FISH as the diagnostic test in daily practice, knowing FISH will miss approximately 10% of cases with LOH at 11q.[115,118] It is important to keep in mind that our current understanding of this entity considers an isolated 11q gain less specific for the entity than a telomeric loss without a gain by FISH. 11q gains without loss have been observed in other entities, making it a less specific finding, whereas the telomeric loss is rarely observed in other entities but may be missed by FISH in cases that show LOH in the respective chromosomal region.[113,115,119,121] For a diagnostic testing strategy, we currently recommend to test only lymphomas with the appropriate morphology and immunophenotype (similar to BL) and absence of *MYC* translocations for this aberration.[119]

DIFFUSE LARGE B-CELL LYMPHOMA/HIGH-GRADE B-CELL LYMPHOMA WITH *MYC* AND *BCL2* REARRANGEMENTS

Definition

Diffuse large B-cell lymphoma/high-grade B-cell lymphoma with *MYC* and *BCL2* rearrangements (HGBL-DH-*BCL2*) is a mature

aggressive B-cell lymphoma defined by coincident chromosomal translocations of *MYC* and *BCL2* (double-hit, DH) and thus shares features with transformed FL even in the absence of preceding or concurrent FL. Concurrent *BCL6* translocations may occur along with *MYC* and *BCL2,* creating a triple-hit. Lymphomas solely harboring *MYC* and *BCL6* translocations can also occur.[122] The ICC considers these as a "provisional entity" requiring further study. These lymphomas are described further at the end of this section.[4] In contrast, the WHO 5th ed. proposal does not currently recognize the *MYC* and *BCL6* translocated cases as a distinct entity.[122] See **Table 23-1** for synonyms and related terms.

Epidemiology

So far, published data on the incidence of HGBL-DH-*BCL2* are based on cohorts from North America and Europe of DLBCL, NOS screened for *MYC* translocations. About 10% of lymphomas morphologically compatible with DLBCL, NOS harbor *MYC* translocations and about half of those carry additional rearrangements of *BCL2,* with or without additional *BCL6* translocations.[123] Thus, about 5% of all lymphomas with the morphology of DLBCL, NOS fulfill the criteria of HGBL-DH-*BCL2*.[123-125] Since L/HGBL-DH is thought to often originate from transformed FL, which is virtually absent in patients under the age of 18 years, L/HGBL-DH is rare in young adults. Thus the true incidence is likely strongly age dependent.

Etiology and Pathogenesis

Formally, the etiology is unknown. However, because the molecular features of HGBL-DH-*BCL2* overlap with transformed FL, it seems reasonable to assume that the etiology should also be similar to FL. However, preceding or coincident FL is detectable in only about one-third of cases by histopathologic analysis.[124,126,127] One might speculate that the true incidence of association with FL is higher as the association is solely defined by histology and thus dependent on biopsy size and sampling. HGBL-DH-*BCL2* carries, by definition, translocations of *MYC* and *BCL2*.

Clinical Features and Staging

Usually DLBCL/HGBL-*MYC/BCL2* presents at an advanced clinical stage and additional features, such as elevated lactate dehydrogenase, leading to a high International Prognostic Index (IPI) score. Extranodal involvement including CNS infiltration seem to be a frequent finding. Staging is currently performed analogous to DLBCL, NOS.[123,128-132]

Morphology

The morphologic spectrum covers a broad range of what may be found in mature aggressive B-cell lymphomas: (1) typical morphology of DLBCL, NOS with centroblasts and immunoblasts to a variable extent; (2) blastoid morphology reminiscent of precursor cell lymphomas or blastic mantle cell lymphoma; and (3) morphology "intermediate" between BL and DLBCL, NOS with small centroblasts and occasionally a starry-sky pattern (**Fig. 23-9**). Most likely, cases with blastoid or "intermediate" morphology are enriched for HGBL-DH-*BCL2*.

Immunophenotype

B-cell markers such as CD20 and CD19 are commonly expressed, and proliferation rate, as assessed by Ki67, is usually high. The vast majority of HGBL-DH-*BCL2s* are positive for CD10[124] and are thus classified as GCB-subtype according to the commonly used cell-of-origin classification developed for DLBCL, NOS.[133] BCL2 is commonly positive too and since the MYC translocations usually lead to MYC overexpression, about 80% HGBL-DH-*BCL2* fall into the category of "double expressors."[134] TdT expression in HGBL-DH-*BCL2* is rare and affects probably far less than 10% of cases. Often only a few cells are TdT positive, but cases with abundant expression of TdT have been reported too.[135-137]

Genetics/Molecular Findings

The translocation partner of *MYC* is mostly the IG heavy chain gene (~60%). The remaining cases show rearrangement of *MYC* to the lambda light chain, *BCL6, PAX5,* or other non-IG genes.[124] The entity is characterized by a complex karyotype and a mutational pattern that overlaps with FL and involves *BCL2, KMT2D, CREBBP, EZH2,* and *TNRSF14*. As a consequence there is considerable overlap of mutational features with transformed FL.[126,138] Most HGBL-DH-*BCL2* fall into the molecular genetic subtypes of DLBCL associated with FL pathogenesis (referred to as EZB,[139] C3,[140] or BCL2 clusters).[141] Diagnostic features are summarized in **Box 23-3**.

What Is, and What Is Not, a Double-Hit?

The current definition of the entity HGBL-DH-*BCL2* does not include cases with *MYC* translocations and translocations of other

genes such as *CCND1*.[142] Cases with gains or amplifications of the *MYC* gene locus without a break/translocation are not considered DLBCL/HGBL-*MYC/BCL2*.[143,144] Of note, sole co-expression of *MYC* and *BCL2* protein, commonly referred to as "double expressor," is far more common than concurrent *MYC* and *BCL2* translocations and does not justify classification as DLBCL/HGBL-MYC/BCL2.

Box 23-3 Diagnostic Criteria for Diffuse Large B-Cell Lymphoma/High-Grade B-Cell Lymphoma With *MYC* and *BCL2* Rearrangements

Key Features

Morphology and phenotype consistent with aggressive B-cell lymphoma

Evidence of concurrent *MYC* and *BCL2* translocations (with or without *BCL6* translocation)

Additional

Germinal-center B cell phenotype

Minimal terminal deoxynucleotidyl transferase protein expression

Determination of *MYC* translocation partner

How to Use Immunohistochemistry to Screen for DLBCL/HGBL-*MYC/BCL2*

Multiple strategies have been discussed about how to prescreen mature aggressive B-cell lymphomas for those that require FISH testing for *MYC/BCL2* DH. Using immunohistochemistry for MYC

and a cutoff of 70% strongly stained nuclei, most cases with underlying *MYC* translocations are detected.[145] However, a considerable number of cases with MYC rearrangements are missed by immunohistochemistry staining. Staining for GCB-type cell of origin may be an alternative to narrow down mature aggressive B-cell lymphomas to those requiring FISH for *MYC*. A recent detailed report describes the performance of each prescreening approach.[125] Focusing on lymphomas with a GCB phenotype would potentially reduce the number of cases that require FISH to approximately 50% in an age-mixed cohort but would potentially detect almost all HGBL-DH-*BCL2* when tested for *MYC* and *BCL2* translocations.[125] Using *MYC/BCL2* "double expressors" as a prescreen may further reduce the number of cases requiring FISH, but for the price of a lower positive predictive value.[125] Given the fact that prospective studies of systematic prescreening by immunohistochemistry has not been yet published, applying FISH for *MYC* to all mature aggressive B-cell lymphomas seems to currently be the most reliable approach for daily practice, followed by reflex testing for *BCL2* rearrangement. Very recent developments of deep learning on digitalized H&E (hematoxylin and eosin)-stained slides raise hope that widely available tools for prescreening may become available in the future.[146,147]

What Is the Role of Gene-Expression Profiling to Identify DLBCL/HGBL-*MYC/BCL2*?

As discussed in the introduction of this chapter, the definition of the disease entity DLBCL/HGBL-*MYC/BCL2* has changed over the last years and is very likely to be further modified in the future. Two

independent approaches identified a gene-expression signature that characterizes DLBCL/HGBL-*MYC/BCL2* (referred to as DH[125] or molecular high-grade signatures).[5] Of note, these gene-expression signatures identify a subset of cases in which *MYC* rearrangements are not identified by FISH, which may be caused by alternate (genetic) mechanisms of MYC activation or alternative mechanism to achieve dark-zone biology.[125] Thus, gene-expression profiling or next-generation sequencing will extend the group of mature aggressive B-cell lymphomas with the biological and clinical features shared with DLBCL/HGBL-*MYC/BCL2* when introduced into the daily practice. It is important to stress that gene-expression profiling also identifies BL as positive for the high-grade signatures.[148] Thus, an independent diagnostic confirmation of the diagnosis is required.

Postulated Cell of Origin

Germinal center B cell.

Clinical Course

The outcome for DLBCL/HGBL-*MYC/BCL2* (40%–50% 5-year overall survival) is reportedly poor compared with DLBCL, NOS.[123] However, most data on survival were collected retrospectively and the outcome may be better in young patients or patients with a low IPI.[129,130] Moreover, a standard treatment has not been defined, although most oncologists tend to treat more intensively than DLBCL, NOS.[131,132]

Does the Translocation Partner of *MYC* Need to Be Determined?

In one study, the poor outcome of DLBCL/HGBL-*MYC/BCL2* is a feature restricted to lymphomas in which *IG::MYC* rearrangement is detectable, whereas DH lymphomas in which *MYC* is partnered to non-IG genes do not substantially differ in outcome from DLBCL, NOS with single *MYC* rearrangements or without any *MYC* rearrangements at all.[123] However, others did not find that translocation partner was associated with outcome.[149] Although the definition of the entity does not require determining the *MYC* translocation partner, the necessity for testing may arise in certain clinical contexts (e.g., when the choice of therapy is discussed in individual patients).

Differential Diagnosis

The most frequent differential diagnoses are outlined in **Table 23-4**. As a genetically defined entity, the differential diagnosis is predominantly based on the detection of a concurrent *MYC* and *BCL2* rearrangement. However, there are several practical considerations helpful to consider in daily practice that will be discussed. Of note, transformed lymphomas should be reported according to their aggressive lymphoma entity followed by adding the term *transformed from* and the denominator of the indolent lymphoma from which it has evolved (e.g., HGBL-DH-*BCL2 transformed from FL* in cases with history or concurrent FL). Other well-defined entities with a DH genetics are also recommended to stay in their original category.

PROVISIONAL ENTITY: HIGH-GRADE B-CELL LYMPHOMA WITH *MYC* AND *BCL6* REARRANGEMENTS

The current definition of HGBL-DH-*BCL2* exclusively includes lymphomas in which translocations of *MYC* and *BCL2* are detected in the same mature aggressive B-cell lymphoma with or without *BCL6* translocation. Lymphomas with translocations of *MYC* and *BCL6* (without *BCL2*) were also previously included in the revised WHO 4th ed. as "high-grade B-cell lymphoma with *MYC* and *BCL2* and/or *BCL6* rearrangements"; however, they are now relocated to a provisional entity by the ICC or classified as DLBCL, NOS or HGBL, NOS (depending on the tumor cell morphology), by the WHO 5th ed. proposal.[4] See **Table 23-1** for synonyms and related terms. These *MYC* and *BCL6* translocated cases differ from HGBL-DH-*BCL2* as they (1) mostly show a non-GCB phenotype and activated B cell (ABC)-like gene expression by cell-of-origin classification,[126] and (2) lack a mutational profile reminiscent of FL but carry mutations *(CD79B, PIM1)* frequently found in ABC-type DLBCL.[140] However, like HGBL-DH-*BCL2* lymphomas, cases with *MYC* and *BCL6* rearrangements show an inferior outcome compared with common DLBCL, NOS.[123] Lymphomas with *MYC* and *BCL6* translocations and morphology not compatible with DLBCL (such as blastoid morphology) may fall into the category of HGBL, NOS.

HIGH-GRADE B-CELL LYMPHOMA, NOT OTHERWISE SPECIFIED

Definition

High-grade B-cell lymphoma, not otherwise specified (HGBL, NOS) is a poorly defined heterogeneous group of mature aggressive B-cell lymphomas that do not fit into other better-defined categories. Its distinction from DLBCL, NOS is predominantly based on a medium-sized blastoid appearance rather than centroblasts and immunoblasts found in DLBCL, NOS and lacks DH genetic features. Cases with features intermediate between DLBCL and BL may be assigned to HGBL, NOS if phenotypic features argue against BL as the diagnosis. See **Table 23-1** for synonyms and related terms.

Epidemiology

As the disease is poorly defined and subjected to changing definitions, the incidence is not known.[112,125,144,148,150]

Table 23-4

Differential Diagnosis of Diffuse Large B-Cell Lymphoma/High-Grade B-Cell Lymphoma With *MYC* and *BCL2* Rearrangements

Entity	Distinguishing Feature
DLBCL, NOS	No difference in morphology or immunophenotype, but by definition, no DH *MYC/BCL2*.
Burkitt lymphoma	*MYC* translocations, but no *BCL2* translocations detected.
High-grade B-cell lymphoma, NOS	No difference in morphology or immunophenotype, but by definition, no DH *MYC/BCL2*.
Precursor B-cell neoplasia	TdT expression usually abundant. Immunophenotypical features of precursor cell neoplasm such as absence/reduction of CD20, expression of CD34, and multilineage phenotype (e.g., with expression of MPO). Molecular analysis may be required in a subset of cases for definite distinction by mutational profile.
Transformed lymphoma	Lymphomas transformed from FL or other low-grade B-cell lymphoma are

Entity	Distinguishing Feature
	considered HGBL-DH-*BCL2* when the respective genetic constellation with *MYC* and *BCL2* translocations is identified, but the information "transformed from FL" should be included in the diagnosis.
Localization specific subtype of LBCL (e.g., CNS or leg-type)	No difference in morphology or immunophenotype, but GCB-phenotype rare in certain entities (cutaneous, CNS, etc.) and DH is rare in any other entity of LBCL. However, if the respective genetic constellation (*MYC* and *BCL2* translocations) is detected, disease is considered DLBCL/HGBL-*MYC/BCL2* irrespective of its clinical presentation.
Classic follicular lymphoma	Follicular growth and cytology with centroblasts and centrocytes (classic FL). Even if DH occurs, these lymphomas appear to clinically behave like typical FL,[157] but additional studies are required to determine the prognostic relevance of MYC in FL.

CNS, Central nervous system; *DH,* double-hit; *FL,* follicular lymphoma; *GCB,* germinal-center B cell; *HGBL,* high-grade B-cell lymphoma; *LBCL,* large B-cell lymphoma; *NOS,* not otherwise specified; *TdT,* terminal deoxynucleotidyl transferase.

Etiology

The etiology of HGBL, NOS is unknown.

Clinical Features and Staging

Clinical features are similar to DLBCL, NOS with a high-intermediate or high International Prognostic Index score. However, most data on the clinical presentation and outcome are based on retrospective analyses and there is considerable uncertainty regarding generalizability.[151,152] Staging is performed analogous to DLBCL, NOS.[128,152]

Morphology

HGBL, NOS is characterized by a diffuse growth of intermediate-to-small-sized blastoid cells with a narrow rim of cytoplasm. These cells do not show features of typical centroblasts and immunoblasts found in DLBCL, NOS (**Fig. 23-10**). Nucleoli are inconspicuous or even absent, similar to cells observed in precursor cell neoplasms or blastoid mantle cell lymphoma.[153] Cases with features intermediate between DLBL and BL may be assigned to HGBL, NOS too if phenotypic features argue against BL as the diagnosis (**Fig. 23-11**).

Immunophenotype

The lymphoma cells show a mature B-cell phenotype with expression of CD20 and CD19 but lack of TdT. When applying the cell-of-origin classification by immunohistochemistry, the majority of HGBL, NOS cases show a GCB-phenotype.[152] Ki67 is variable but usually lower than seen in BL. Since *MYC* translocations occur frequently in this

rare subtype of mature aggressive B-cell lymphomas, expression of MYC can be detected in a substantial number of cases.[150,154,155]

Genetics/Molecular Findings

As a poorly defined entity, it is not surprising that the molecular features are heterogeneous. The mutational profile of these lymphomas, for example, identifies cases with more GCB-like and others with more ABC-like mutational profiles.[148]

However, three features are rather consistent and may also be helpful for diagnosis and management. First, HGBL, NOS is characterized by a high rate of *KMT2D* (43) and *TP53* mutations (30%).[144] Second, *MYC* translocations (by definition without concurrent *BCL2* translocations) and *MYC* amplifications are frequent (~8%–58% reported).[112,144,150] Third, gene-expression analysis assigns a large number of cases (54%) to the group with a DH signature.[125] A summary of the diagnostic features are located in **Box 23-4**.

Postulated Cell of Origin

Germinal center B cell.

Clinical Course

Treatment guidelines have not been defined. Some physicians treat according to DLBCL, NOS whereas others prefer to use intensified regimens.[152] Overexpression of both MYC and BCL2 ("double expresser") has been linked to inferior outcome.[155]

Differential Diagnosis

HGBL, NOS is a diagnosis of exclusion. In any case with blastoid or intermediate cell morphology, a DLBCL/HGBL-DH-*MYC/BCL2* should be excluded by FISH for *MYC* and *BCL2*. Expression of CD10, Ki67 of more than 90%, absence of BCL2 expression, and the presence of a *MYC* translocation should raise suspicion of BL. It has been shown that lymphomas with the phenotype of BL but absence of typical BL morphology molecularly resemble BL. Absence of BCL2 expression is typical of HGBL, NOS.[112] It is noteworthy to mention that morphologic features of BL, such as the starry-sky pattern, disappear when tissue processing is suboptimal, which might lead to an overdiagnosis of HGBL, NOS, especially in young patients. Differential diagnosis features for these cases are summarized in **Table 23-3**.

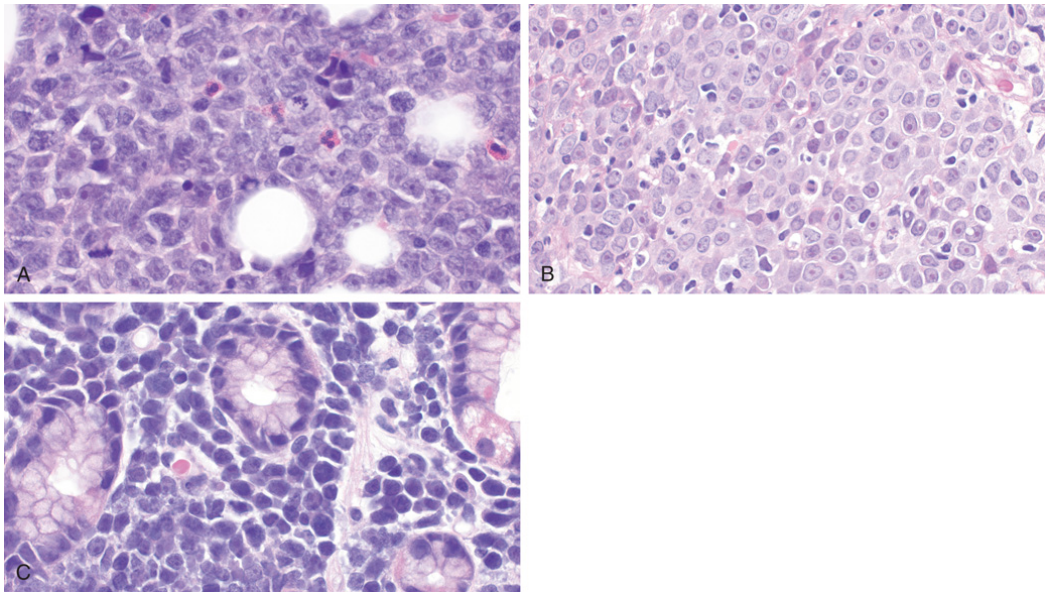

FIGURE 23-10 Morphologic variability of HGBL-DH-*BCL2* with multiple examples showing a range of differentiation with centroblastic **(A)**, immunoblastic **(B)**, or blastoid morphology **(C)** (H&E). All lymphomas were shown to harbor *MYC* and *BCL2* translocations.

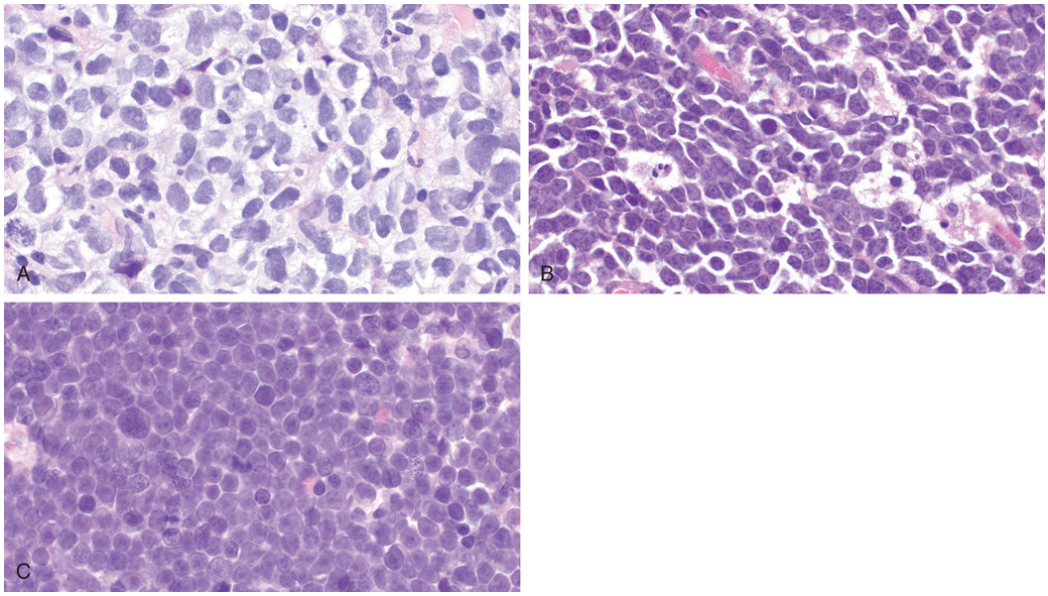

FIGURE 23-11 Morphologic variability of three cases of high-grade B-cell lymphoma, not otherwise specified (H&E). Polymorphic large cells with abundant cytoplasm **(A)**, dense sheets of medium-sized blasts reminiscent of Burkitt lymphoma **(B)**, and small blasts with very narrow rim of cytoplasm similar to lymphoblastic lymphoma **(C)**.

Box 23-4 Diagnostic Criteria for High-Grade B-Cell Lymphoma, Not Otherwise Specified

DH, Double-hit; *HGBL-11q,* high-grade B-cell lymphoma with 11q aberration; *MCL,* mantle cell lymphoma; *TdT,* terminal deoxynucleotidyl transferase.

Key Features

Intermediate or blastoid cytomorphology not consistent with either diffuse large B-cell lymphoma or Burkitt lymphoma

Lack of TdT, CD34 to exclude lymphoblastic lymphoma; lack of cyclin D1 to exclude blastoid MCL

Absence of a dual translocation (DH) involving *MYC* and *BCL2*

Absence of the 11q gain/loss pattern of HGBL-11q

Additional Features

DH B-cell lymphoma gene expression signature

KMT2D and *TP53* mutations

Cases with blastoid morphology and follicular growth should be diagnosed as one of the unusual variants of FL.[156] To identify follicular growth pattern, detection of follicular dendritic cells by staining for CD21 or CD23 can be helpful. Blastoid variants of mantle cell lymphoma need to be distinguished from HGBL, NOS by staining for cyclin D1 and SOX11. Precursor cell lymphoma needs to be excluded by staining for TdT and CD34.

Pearls and Pitfalls

- Be aware that slightly nuclear irregularity and variation in cell size and shape may be caused by fixation or processing artifacts and do not preclude a diagnosis of Burkitt lymphoma (BL). The starry-sky pattern is particularly prone to vanish in poor tissue quality. B5 fixation tends to make cells appear smaller with a single, central nucleolus.

- Weak BCL2 protein expression may be encountered in BL. However, in all cases with any doubt, in particular in non-pediatric patients, the diagnosis should be further substantiated with molecular additional techniques in addition to morphology and immunophenotype.
- Have a low threshold for performing fluorescence in situ hybridization (FISH).
- If a diagnosis of BL is being considered and the results of the cytogenetic studies are available, they should show either a t(8;14) or a variant translocation. Three-way translocations and cryptic translocations that need additional FISH analysis can incidentally be observed in BL.
- If all other criteria of classic BL are met but *MYC* FISH is negative, testing for 11q aberrations is strongly suggested.
- Variant *MYC* translocations require cytogenetic analysis or the use of locus-specific FISH studies. A *MYC* break-apart assay may be negative despite presence of *MYC* translocations.
- The most commonly encountered de novo lymphoma (outside of endemic BL areas) with *MYC* translocation are high-grade B-cell lymphoma (HGBL) and diffuse large B-cell lymphoma (DLBCL) (5%–15% of de novo DLBCL). More than half of those are HGBL with double-hit (DH) with *MYC* and *BCL2* translocations.
- HGBL-DH is strictly defined by rearrangements of both *MYC* and *BCL2* or *BCL6* and includes cases with DLBCL morphology. Cases with other molecular abnormalities (mutations, gain, or amplification without a concomitant

breakpoint) of these genes or rearrangements of other genes such as *CCND1* should not be included.

- Although they also have a poor prognosis, the more common DLBCL with double expression of MYC and BCL2 protein (DLBCL "double expressers") should not be mixed up with HGBL-DH.
- DH in follicular lymphoma without any clinical and pathology evidence of transformation and precursor lymphoma blastic lymphoma/leukemia are excluded from HGBL-DH.

Genetic Features

Differential Diagnosis

This chapter reviews two aggressive large B-cell lymphomas composed of large cells with a predominant immunoblastic or plasmablastic morphology and the immunophenotype of plasma cells. Despite sharing these morphologic and immunophenotypical features, plasmablastic lymphoma (PBL) occurs in patients with immunodeficiency or advanced age, and most cases are related to Epstein-Barr virus (EBV) infection. Conversely, ALK-positive large B-cell lymphoma occurs in immunocompetent patients, and it is caused by the activation of ALK by different translocations. The morphologic and immunophenotypical features of these lymphomas are also shared by human herpesvirus 8 (HHV-8)–related aggressive lymphomas, which are reviewed in **Chapter 29**. The recognition of all these entities may raise differential diagnoses with related tumors on both sides of the spectrum, such as diffuse large B-cell lymphomas (DLBCLs) and plasma cell neoplasms. The distinction is important because the clinical context and management of these patients may differ.

Plasmablastic Lymphoma

Definition

PBL is a diffuse lymphoma composed of large B cells with a predominant morphology of immunoblasts or plasmablasts that

express plasma cell differentiation antigens.[1] PBL may also occur as a transformation from low-grade B-cell lymphomas.[2,3] Other subtypes of large B-cell lymphoma with a plasmablastic immunophenotype, such as ALK-positive large B-cell lymphomas and HHV-8–associated lymphoproliferative disorders, are not included in this category.

The term *plasmablastic lymphoma (PBL)* was introduced by Delecluse and colleagues in 1997 to describe a group of DLBCLs presenting in the oral cavity and jaws of individuals infected with HIV.[4] These tumors showed immunoblastic morphology with an immunophenotype characteristic of plasma cells. Subsequently, PBL has been described in other localizations, mostly in gastrointestinal mucosa, and has been associated with other immunodeficiency states and advanced age.[5-7]

Synonyms

None.

Epidemiology

This lymphoma occurs predominantly in adults with immunodeficiency and is most commonly caused by HIV infection, but it is also associated with iatrogenic immunosuppression (transplant and autoimmune diseases). Some cases arise in older adult patients without an apparent cause of immunodeficiency other than possible immunosenescence, and in children with immunodeficiency, mainly HIV infection.[4,5,7,8] Patients who are HIV positive tend to be younger than those with other types of immunosuppression.[8]

Clinical Features

The clinical presentation is frequently as a tumor mass in extranodal regions of the head and neck, in particular the oral cavity, and less frequently in the nasal cavity or respiratory sinuses. Other sites commonly involved are the gastrointestinal tract, soft tissues, skin, bone, lung, and less frequently, the lymph nodes.[5-8] Nodal presentation is more frequent in posttransplant-associated PBL (30%) than in patients infected with HIV or older adult patients (<10%).[5] Computerized image exploration may detect disseminated bone lesions in 30% of patients.[9] Paraprotein may be detected in some cases.[10] Disseminated stage III/IV disease at presentation, including bone marrow involvement, occurs in 75% of patients who are HIV positive and 50% of patients with posttransplant disease, but only in 25% of patients without apparent immunodeficiency.[5,7]

The prognosis is generally poor, with more than three-quarters of patients dying of the disease at a median interval of 6 to 7 months.[4,5,7,11] Some reports observed patients with longer survival related to new antiretroviral treatments, better immunologic status, and improvements in supportive care and delivery of chemotherapy. However, these results are not consistent among studies.[5] Evaluation of prognostic parameters have not yielded consistent results. However, the presence of the *MYC* translocation has been associated with poorer outcomes in two studies.[5]

Pathology

Histologically, two variants have been recognized: monomorphic PBL and PBL with plasmacytic differentiation. Monomorphic PBL is composed of a diffuse and cohesive proliferation of immunoblasts or

large cells with minimal or no morphologic plasma cell differentiation. Cases with plasmacytic differentiation have cells with rounder and eccentric nuclei, coarse chromatin, abundant basophilic cytoplasm, and paranuclear hof (**Fig. 24-1**). Intermediate features between these monomorphic and plasmacytic variants may be seen in some cases. Monotypic maturing plasma cells may be occasionally present. A starry sky pattern is common in monomorphic cases with high mitotic activity and abundant apoptotic bodies. The border of the tumor infiltration is sometimes relatively well delimited, and areas of geographic necrosis are not uncommon (**Fig. 24-2**).

The immunophenotype is similar to that of plasma cells with negative expression of CD45, CD20, and PAX5. A variable expression of CD79 may be seen in approximately 40% of the tumors. On the contrary, the tumor cells express plasma cell–associated markers and transcription factors such as CD38, CD138, VS38c, IRF4/MUM-1, BLIMP1, and XBP1[12] (**Fig. 24-3**). Variable expression of cytoplasmic immunoglobulin (Ig) may be seen. BCL2 and BCL6 expression is usually negative, whereas CD10 is expressed in 20% of cases. Epithelial membrane antigen (EMA) and CD30 are frequently expressed, and CD56 is detected in 25% of cases. MYC is usually overexpressed, even in cases without rearrangement.[13] The tumors have a high proliferation (Ki-67) index (>90%). Reactive infiltrating T cells are usually very scarce.[4,5,7,11,14] Some PBL might aberrantly express T-cell markers, mainly CD3 or CD4, a pitfall that should be considered. This feature is also described in occasional plasmablastic multiple myelomas.[14-16]

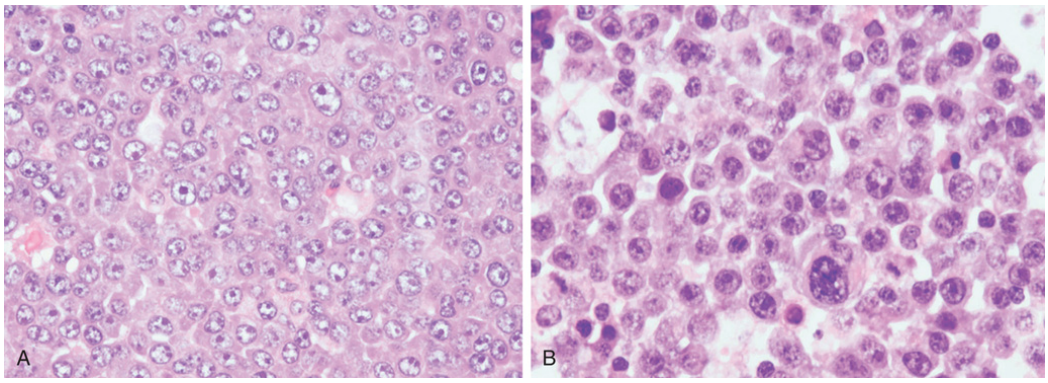

FIGURE 24-1 Plasmablastic lymphoma, cytologic variants.**A,** Monomorphic variant with large cohesive immunoblastic cells. **B,** Plasmacytic variant composed of large cells with round eccentric nuclei and coarser chromatin.

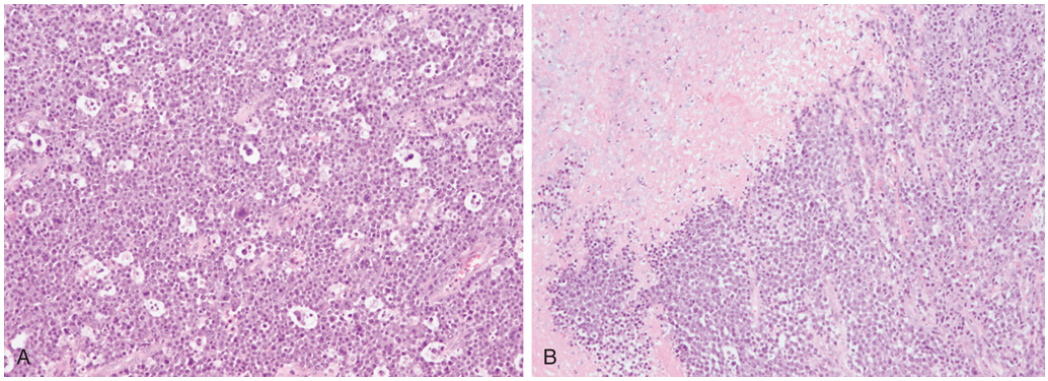

FIGURE 24-2 Plasmablastic lymphoma.**A,** A starry-sky pattern at low power may suggest Burkitt lymphoma. **B,** Areas of geographic necrosis may be seen in some cases.

Genetic Features

EBV is positive in 70% of cases, usually with latency type I, although occasional cells may express LMP1 (**Fig. 24-4**). PBL in HIV-positive and posttransplant cases is more frequently EBV positive than in HIV-negative cases.[5,8] HHV-8 is always negative.[4,7,11,17]

Genetic studies have revealed frequent complex karyotypes and specific alterations, such as gains of 12p and 16q11.2-q24.3 CNN-LOH, which may be used in the differential diagnosis with other entities.[18] *MYC* translocations have been identified in approximately 50% of cases, more in EBV-positive (74%) than EBV-negative tumors (43%), and they are associated with MYC protein expression.[19] The rearrangement usually occurs with IG genes. *MYC* amplification occurs in some cases.[13] MYC expression in normal terminal B-cell differentiated cells is suppressed by BLIMP1, a transcription factor required for plasma cell differentiation.[20] Therefore, the activation of *MYC* by an oncogenic mechanism may be important for the pathogenesis of the disease to overcome the repressor effect of BLIMP1 and provide the tumor cells with a proliferative and survival advantage (**Fig. 24-5**).[19]

Genomic studies have revealed genetic alterations activating the MAPK and JAK-STAT pathways as the predominant drivers of PBL lymphomagenesis.[18,21-23] The genetic profiles in these tumors are slightly different in relation to EBV and HIV infections. Specifically, EBV-negative PBL harbors a higher mutational and copy number load with more mutations affecting epigenome/chromatin modifiers and more frequent *TP53, CARD11,* and *MYC* mutations. Conversely, EBV-positive PBL tends to have more *STAT3* and *SOCS1* mutations. HIV-negative cases seem to carry *STAT3* and *LNP1* mutations less frequently but *TP53, PRDM1,* and *IRS4* mutations more frequency,

in addition to alterations involving the MAPK pathway. The genomic profile of PBL is different from those of activated B-cell-like (ABC)-DLBCL and multiple myeloma; therefore, sequencing analysis may assist in the differential diagnosis. Particularly, *STAT3, NRAS,* and *EP300* mutations are frequently seen in PBL, whereas *STAT3* and *EP300* are rare in multiple myeloma, and *NRAS* and *STAT3* mutations are uncommon in ABC-DLBCL (**Fig. 24-6**).[24-26]

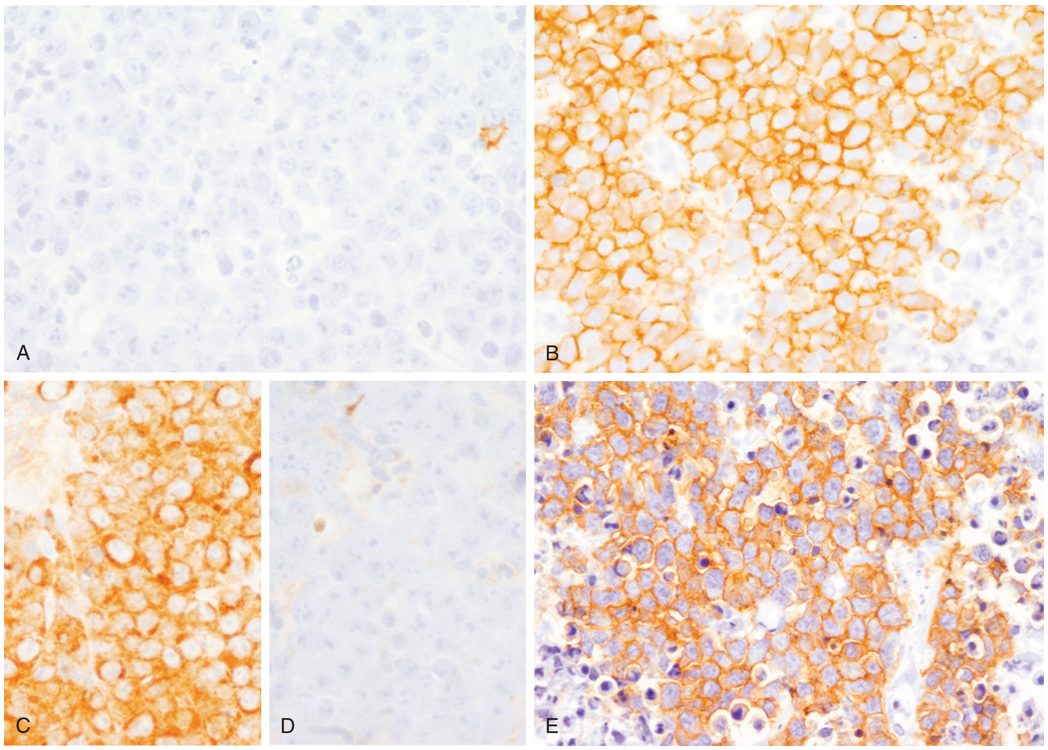

FIGURE 24-3 Plasmablastic lymphoma phenotype.**A,** Plasmablastic lymphoma is CD20 negative. **B,** Tumor cells expressed the plasma cell–associated marker CD138. Kappa **(C)** but not lambda **(D)** expression. **E,** Epithelial membrane antigen is often positive.

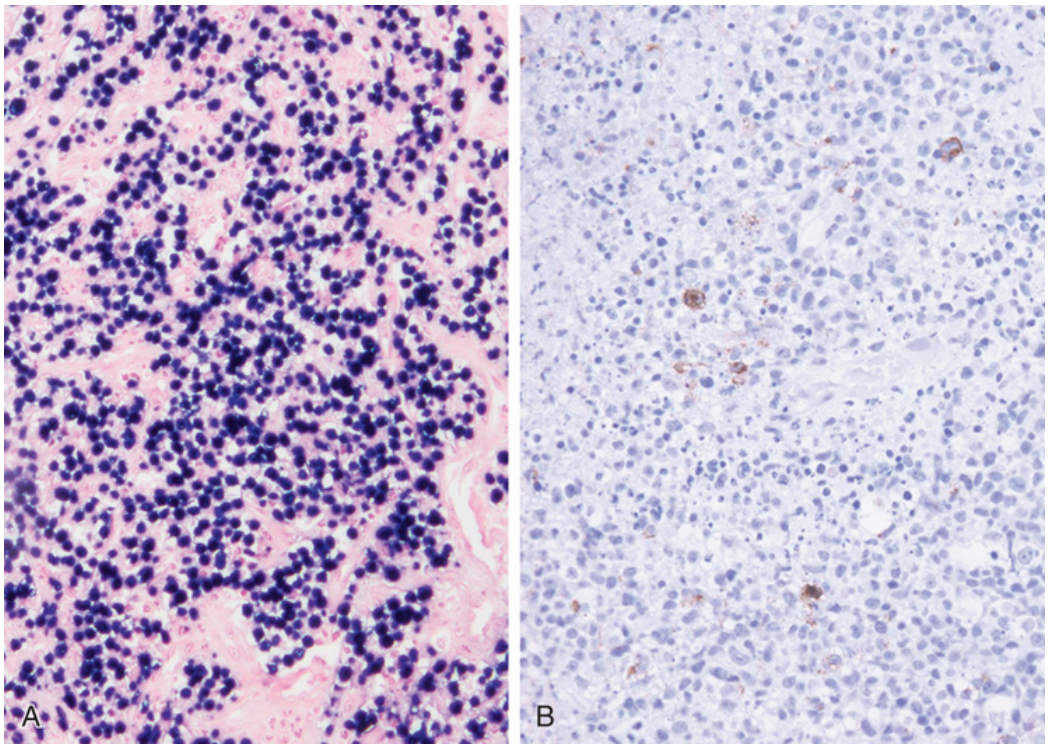

FIGURE 24-4 EBV in plasmablastic lymphoma.**A,** Epstein-Barr encoding small RNA (EBER) in situ hybridization shows the presence of Epstein-Barr virus (EBV) in virtually all tumor cells. **B,** Immunostaining of LMP1 is usually negative or only positive in very few cells.

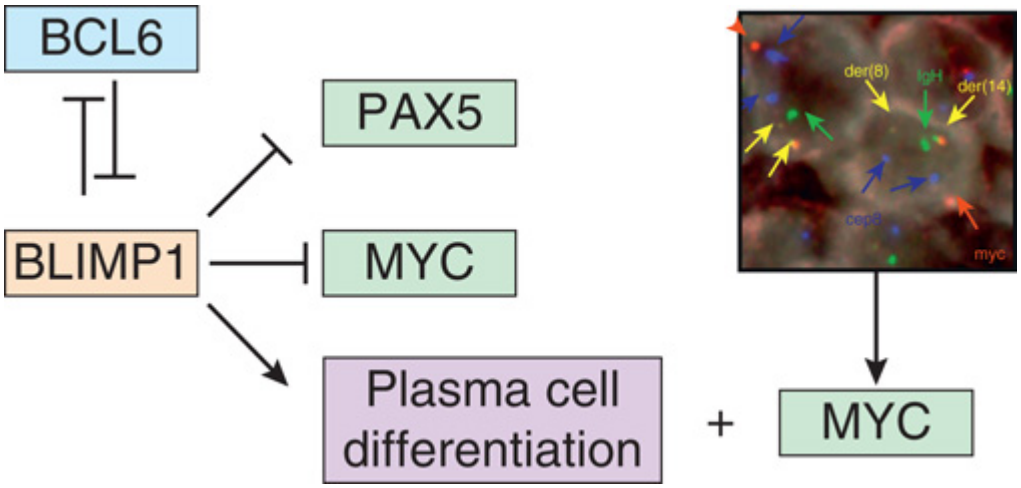

FIGURE 24-5 Molecular pathogenesis in plasmablastic lymphoma.Plasmablastic lymphomas express the transcription factor BLIMP1 required for plasma cell differentiation. However, BLIMP1 represses *MYC*. The activation of *MYC* by the oncogenic translocation t(8;14) may be important to overcome the repressor effect of BLIMP1 and provide the tumor cells with a proliferative and survival advantage.

Differential Diagnosis

The differential diagnosis of PBL must be established with other large B-cell lymphomas with terminal B-cell differentiation and anaplastic/plasmablastic plasma cell neoplasms that share similar morphology and overlapping phenotypic features. The absence of smaller neoplastic cells with plasmacytic differentiation was originally thought to be a feature that could distinguish PBL from plasmacytoma,[4] but it is now recognized that these cells are present in some cases.[7,11] CD56 expression tends to occur more frequently in

plasma cell neoplasms, but it also occurs in some PBLs and therefore cannot be used as a definitive criterion.[7,14] Cyclin D1 is negative in PBL but positive in a subgroup of patients with multiple myeloma. The clinical presentation (immunodeficiency, oral involvement, absence of multiple myeloma), high proliferation index, and frequent EBV association are features supporting a diagnosis of PBL over anaplastic/plasmablastic plasma cell neoplasms. However, some cases occurring in patients who are HIV positive have overlapping features with multiple myelomas such as lytic bone lesions and monoclonal serum immunoglobulins.[7,14] Identification of *STAT3, TET2,* or *EP300* mutations may favor PBL over multiple myeloma (**Fig. 24-6**).[26] In some cases, a firm distinction cannot be made, and a descriptive diagnosis such as *plasmablastic neoplasm, indeterminate between PBL and anaplastic plasmacytoma* may be acceptable.

The starry-sky pattern and the high proliferation index may suggest a diagnosis of Burkitt lymphoma. However, the cells in PBL are larger and do not express CD20, whereas the cells in Burkitt lymphoma are negative for plasma cell–associated markers. The presence of EBV may raise the differential diagnosis of EBV-positive DLBCL, not otherwise specified (NOS).[27] However, mature B-cell markers (although weak or negative in some cells) are still extensively expressed in these cases, and contrary to PBL, tumor-infiltrating T cells are abundant.

Some cases of DLBCL, NOS may have morphologic features similar to PBL, with eccentric nuclei, basophilic cytoplasm, and strong immunoglobulin cytoplasmic expression.[28] However, contrary to PBL, the tumor cells express strong CD20, CD79a, and

PAX5 and have frequent *TP53* alterations. Clinically, the patients do not have immunodeficiency, but the prognosis is also poor. The mutational profile may assist in the differential diagnosis, as *NRAS* and *STAT3* mutations are common in PBL and infrequent in ABC-DLBCL (**Fig. 24-6**).[25] Large B-cell lymphomas related to HHV-8 infection usually have plasmablastic features.[29-31] However, these tumors are caused by different diseases that must not be confused with PBL (see **Chapter 29**).

Large B-cell lymphomas with plasmablastic features may occur as a rare transformation of small B-cell lymphoid neoplasms, mainly chronic lymphocytic leukemia and follicular lymphoma.[2,3] These cases may occur as a relapse or may be detected at diagnosis simultaneously with the small-cell lymphoma component. A clonal relationship may be confirmed either by IGHV rearrangement analysis or the identification of similar genetic alterations in both components. These cases are similar to conventional PBL, but immunodeficiency does not seem to play a role, and EBV infection or *MYC* translocation are only rarely seen.[3]

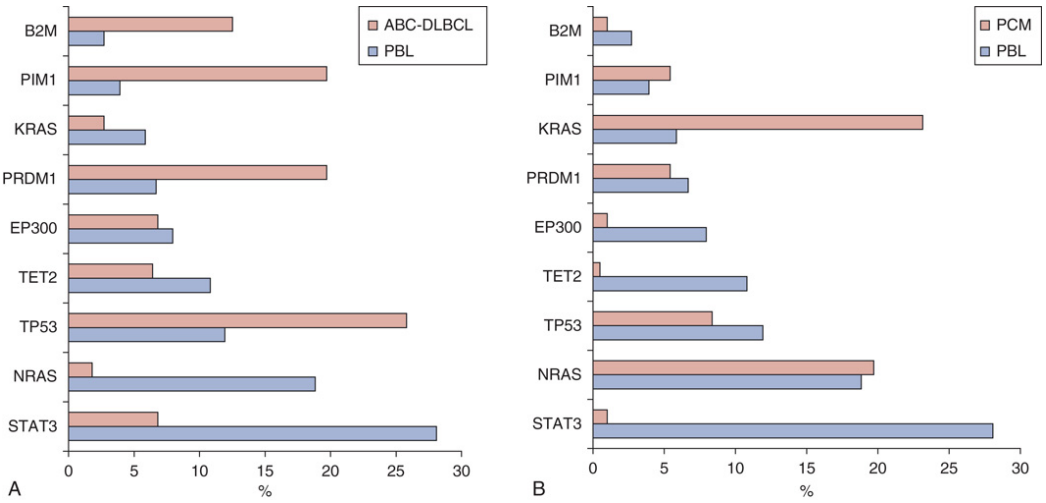

FIGURE 24-6 Comparison between mutations in plasmablastic lymphomas and other related lymphoid neoplasms.Percentage of mutated cases in PBL from five different series[19,22-24,42] compared with **(A)** 295 cases of activated B-cell diffuse large B-cell lymphoma (ABC-DLBCL)[43] and **(B)** 203 cases of multiple myeloma[44] including the most frequently mutated genes interrogated in those series.

Alk-Positive Large B-Cell Lymphoma

Definition

ALK-positive large B-cell lymphoma (ALK-positive LBCL) was initially described by Delsol and colleagues in 1997[32] as an uncommon and aggressive subtype of DLBCL with frequent immunoblastic morphology that expressed a plasma cell immunophenotype and the ALK protein.

Synonyms

None.

Epidemiology

This tumor is very uncommon (<1% of DLBCLs) and occurs predominantly in young adults (median age approximately 40 years) but may present in patients with a broad range of age (9 to 90 years). Around 30% of these lymphomas are diagnosed in childhood. The male-to-female ratio is 5:1.[1,33]

Clinical Features

Most patients present with generalized lymphadenopathy, although occasional cases have been reported in extranodal sites including the nasal cavity, gastrointestinal tract, liver, spleen, soft tissues, skin, and bone. There is no association with immunosuppression. Bone marrow may be infiltrated in 33% of cases. The majority of patients (61%) have high-stage (III to IV) disease. The evolution is aggressive, and the outcome poor, with around half of the patients dying within the first year after diagnosis. Five-year overall survival is only 28%. Patients presenting with localized disease (stage I to II) had a significantly longer survival.[33]

Pathology

The tumor is composed of a diffuse and very monotonous proliferation of large cells with immunoblastic or plasmablastic appearance. The nuclei are vesicular and usually have a large central nucleolus. The cytoplasm is abundant and basophilic. Multinucleated cells may be present (**Fig. 24-7**). The lymph nodes are usually massively infiltrated, and a more or less prominent sinusoidal

growth pattern is seen in most cases (**Fig. 24-8**). The tumor cells may appear very cohesive and thus may be misinterpreted as carcinoma cells. Focal necrosis can be seen.[34]

These cells are negative or only occasionally positive in very few cells for the mature B-cell markers CD20, CD79, and PAX5. However, they express CD45 (80%), although usually weak, EMA (100%), IRF4 (73%), and kappa or lambda light chain (90%), most often associated with IgA (**Fig. 25-7**).[34] The plasma cell–related antigens CD138, BLIMP1, and XBP1 are diffusely expressed in virtually all cases (**Fig. 24-7**). CD30 is usually negative or only weak and focal (6%). CD4 expression may be seen in 40% of tumors and CD57 in some cases. Other T-cell markers are negative. Cytokeratin expression has rarely been described, adding to the possible confusion with metastatic carcinoma, especially in combination with EMA positivity.[35] All cases are EBV and HHV-8 negative.[34]

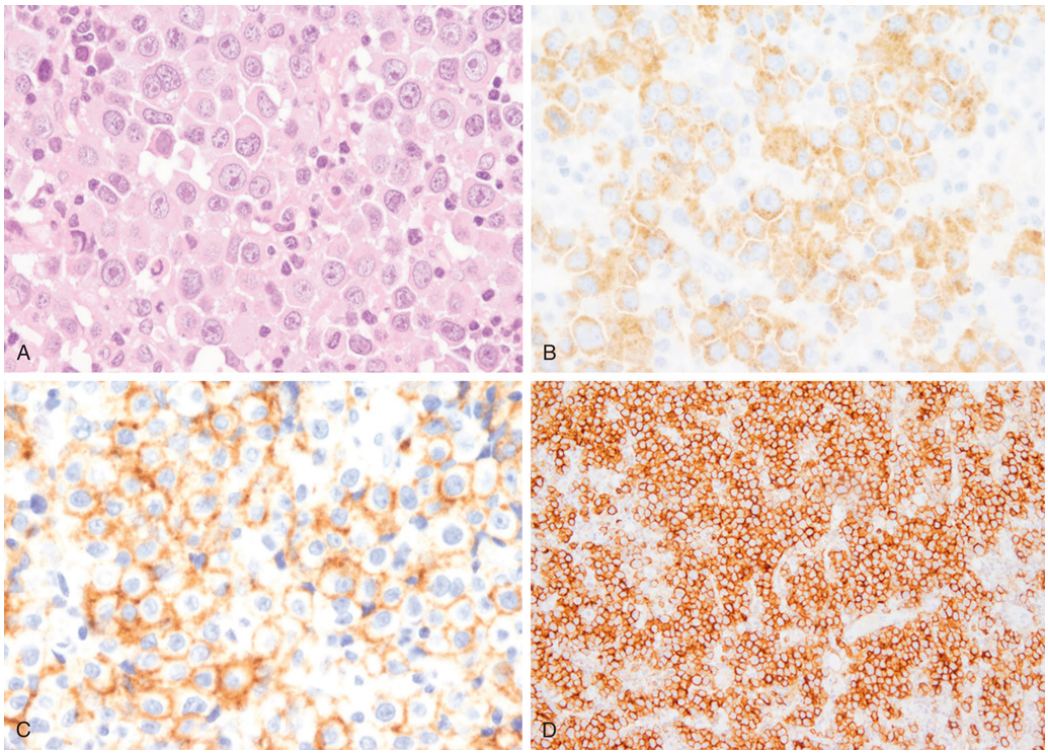

FIGURE 24-7 ALK-positive large B-cell lymphoma.**A,** This tumor is composed of large cohesive cells with immunoblastic features. **B,** ALK is expressed with a granular cytoplasmic pattern suggestive of the t(2;17)(p23;q23) translocation, which leads to the fusion of *ALK* with *CLTC* (clathrin). **C,** The plasma cell–associated marker CD138 is expressed in tumor cells. **D,** Epithelial membrane antigen is strongly positive in tumor cells.

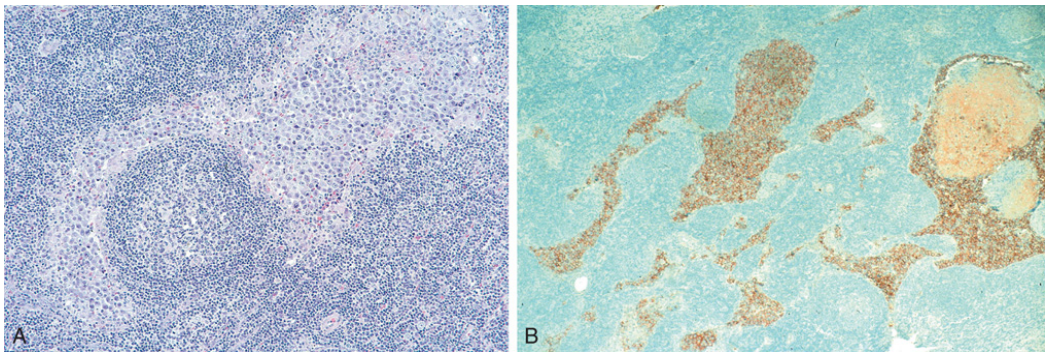

FIGURE 24-8 ALK-positive large B-cell lymphoma.**A,** Sinusoidal infiltration. **B,** Epithelial membrane antigen expression in intrasinusoidal tumor cells. Courtesy NL Harris

By definition, this lymphoma expresses ALK, with staining frequently confined to the cytoplasm with a granular pattern that is associated with the *ALK-CLTC* (clathrin) translocation (**Fig. 24-7**). In cases with the *ALK-NPM* translocation, ALK staining is nuclear and cytoplasmic. Homogeneous cytoplasmic staining may be seen with other less common *ALK* translocations. These different immunohistochemical ALK patterns result from the normal distribution of the fusion partner protein. Thus, clathrin is a protein of the membrane of cytoplasmic vesicles, whereas NPM shuttles proteins between the cytoplasm and nucleus.[34]

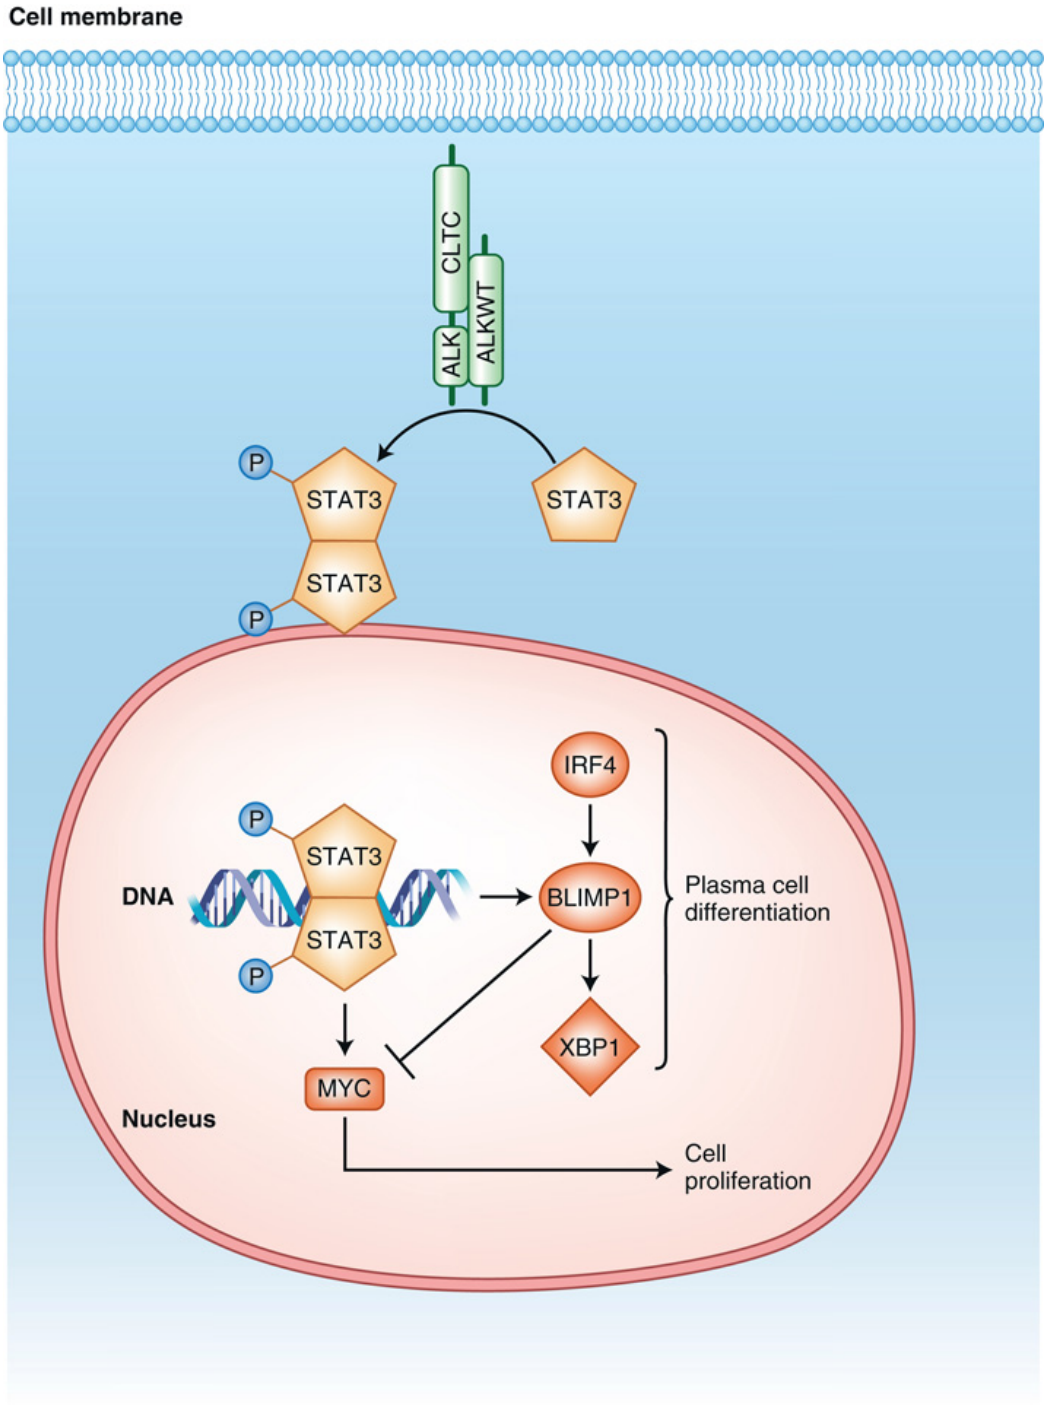

FIGURE 24-9 ALK-positive large B-cell lymphoma pathogenesis.ALK expression in these lymphomas is activated by translocations that, in turn, activate STAT3. A downstream effector of

STAT3 is BLIMP1, which promotes the plasma cell differentiation process, and MYC, which is normally repressed by BLIMP1. MYC is also expressed in ALK-positive large B-cell lymphoma pathogenesis in the absence of gene translocations or amplifications.

Genetic Features

These tumors are genetically characterized by *ALK* translocations that activate gene expression. The most common is the t(2;17)(p23;q23) translocation, which leads to fusion of *CLTC* (clathrin) with *ALK*.[36,37] Rare cases with the t(2;5)(p23;q35) *(NPM-ALK)* translocation have also been reported.[38,39] Other uncommon fused genes to *ALK* are *SQSTM1, SEC31A,* and others.[34,40-43] These translocations are detected in the context of complex karyotypes.

ALK is a tyrosine kinase receptor that is not normally expressed in B lymphocytes or T lymphocytes. *ALK* rearrangements upregulate the expression of oncogenic fusion genes, in which the ALK fragment contains the catalytic domain and the fused partner provides a dimerization domain that activates the receptor without the need of the ligand. ALK oncogenic mechanisms include activation of the STAT3 pathway and, concordant with these experimental observations, ALK-positive LBCLs express high phospho-STAT3.[40] A downstream effector of STAT3 is BLIMP1, which promotes the plasma cell differentiation process, and it is also always expressed in these tumors. On the other hand, STAT3 also upregulates MYC, which is normally repressed by BLIMP1. Concordant with these mechanisms, MYC is also expressed in ALK-positive LBCL in the

absence of gene translocations or amplifications (**Fig. 24-9**).[40] Experimental studies in a murine model have shown that forced expression of ALK in B cells generates large B-cell tumors with plasmablastic features that may correspond to an experimental counterpart of this human tumor.[44]

Differential Diagnosis

ALK-positive LBCL should be distinguished from ALK-positive anaplastic large-cell lymphoma (of T-cell/null-cell phenotype), PBL, and DLBCL-NOS with a sinusoidal growth pattern. The cohesive pattern of the cells, sinusoidal infiltration, lack of mature B-cell markers, and occasional expression of cytokeratins may raise the diagnosis of melanoma or carcinoma.

Pearls and Pitfalls

- B-cell lymphomas with large-cell morphology and expressing plasma cell markers encompass a diverse group of entities. Differential diagnosis requires a combination of pathologic and clinical information and the detection of specific markers such as EBV, HHV-8, or ALK. The mutational profile may assist in the differential diagnosis.
- PBL is frequently associated with a background of immunodeficiency caused by different mechanisms, but it can also be detected in apparently immunocompetent patients, usually of advanced age.

- The differential diagnosis between PBLs and plasma cell neoplasms with anaplastic/plasmablastic features relies on the clinical history of immunodeficiency, previous evidence of other manifestations of plasma cell tumors, or EBV infection. The different mutational profile may also orient the differential diagnosis. However, there are cases with overlapping features, and a clear distinction is not always possible.
- DLBCL with morphologic plasma cell differentiation and expression of mature B-cell markers such as CD20 or PAX5 and strong cytoplasmic immunoglobulin expression should not be considered PBL.
- ALK-positive LBCL should be considered in the differential diagnosis of large-cell tumor with sinusoidal infiltration in a lymph node in the absence of a clear primary solid tumor.

Classification Of Plasma Cell Neoplasms

Definition

Plasma cell neoplasms (PCNs) and related disorders are clonal proliferations of immunoglobulin (Ig)-producing plasma cells (PCs) or lymphocytes that make and secrete a single class of Ig or a polypeptide subunit of a single Ig that is usually detectable as a monoclonal protein (M protein) by serum or urine protein electrophoresis. These immunosecretory disorders may consist exclusively of PCs or a mixture of PCs and lymphocytes. The latter are generally categorized as lymphomas and are discussed elsewhere in this book. PCNs are the subject of this chapter. Most of these are bone marrow–based neoplasms, but they occasionally develop in extramedullary sites.

Classification

The categories of PCNs recognized in the published International Consensus Classification (ICC) and the proposed 5th edition of the World Health Organization (WHO) Classification of Tumours of Haematopoietic and Lymphoid Tissues are indicated in **Boxes 25-1**

and **25-2**, respectively.[1,2] ICC nomenclature will be used in this chapter.

Pathogenesis of Plasma Cell Neoplasms

Clinical studies in the 1970s led to the proposal of a pathogenetic pathway in which multiple myeloma (MM) evolves from the precursor state, monoclonal gammopathy of undetermined significance (MGUS), with progression to a "smoldering" phase, ultimately culminating in development of symptomatic MM and necessitating therapeutic intervention.[3] Disease progression of MGUS occurs at a low frequency in affected individuals, whereas some 10% of patients with smoldering MM (SMM) progress each year to symptomatic disease. MGUS was established as an obligatory precursor state in MM through the retrospective analyses of biorepository samples, which confirmed the presence of serum M protein years prior to the development of clinically overt disease in virtually all patients with MM.[4,5]

Box 25-1 International Consensus Classification of Plasma Cell Neoplasms

- Monoclonal gammopathy of undetermined significance (MGUS)
  - Non-IgM MGUS
  - IgM MGUS, plasma cell type
- Multiple myeloma (plasma cell myeloma)
  - Multiple myeloma, not otherwise specified (NOS)
  - Multiple myeloma with recurrent genetic abnormality
- Multiple myeloma with *CCND* family translocation

- Multiple myeloma with *MAF* family translocation
- Multiple myeloma with *NSD2* translocation
- Multiple myeloma with hyperdiploidy
- Solitary bone plasmacytoma (SBP)
    - SBP without bone marrow involvement
    - SBP with minimal bone marrow involvement (<10%)
- Solitary extraosseous plasmacytoma
- Monoclonal immunoglobulin deposition diseases
    - Immunoglobulin light chain amyloidosis (AL)
    - Localized AL amyloidosis
    - Light chain and heavy chain deposition

Box 25-2 World Health Organization Classification (Proposed 5th Edition) of Plasma Cell Neoplasms

Monoclonal Gammopathies

- Cold agglutinin disease
- IgM monoclonal gammopathy of undetermined significance (MGUS)
- Non-IgM MGUS
- Monoclonal gammopathy of renal significance

Plasma Cell Neoplasms

- Plasma cell myeloma

- Solitary plasmacytoma of bone (SPB)
  - SBP without bone marrow involvement
  - SBP with minimal bone marrow involvement (<10%)
- Extramedullary plasmacytoma (EMP)
- Plasma cell neoplasms with associated paraneoplastic syndrome
  - POEMS syndrome
  - TEMPI syndrome
  - AESOP syndrome

Diseases With Monoclonal Immunoglobulin Deposition

- Immunoglobulin-related (AL) amyloidosis
- Localized AL amyloidosis
- Monoclonal immunoglobulin deposition disease

Heavy Chain Diseases

- μ heavy chain disease
- γ heavy chain disease
- α heavy chain disease

The genetics of PC neoplasms have been extensively studied in the past 2 to 3 decades, and the overarching pathogenetic feature that has emerged is that of progressive genomic instability. The initiating genetic lesions, mostly identified using conventional cytogenetic approaches, define two major subtypes of MM, namely hyperdiploidy and Ig heavy chain (IGH) gene translocation-associated (**Table 25-1**).[6-8] The hyperdiploid group accounts for about 60% of cases and is

characterized by trisomies of odd-numbered chromosomes: 3, 5, 7, 9, 11, 15, 19 and 21 (**Fig. 25-1**).[6,9-11] The *IGH* translocation group in which the IGH locus on chromosome 14q32 is targeted accounts for 40% of myelomas. *IGH* translocations have been identified that target one of several recurrent partner genes, including the cyclin D genes (*CCND1,* 11q13, 15% of cases; *CCND2,* 12p13, <1% of cases; and *CCND3,* 6p21, 2% of cases); *NSD2/FGFR3* (4p16.3, 15% of cases); and *MAF* genes (*CMAF,* 16q23, 5% of cases; *MAFB,* 20q11, 2% of cases; and *MAFA,* 8q24, <1% of cases).[6,8,11-13] Hyperdiploidy and *IGH* translocations are largely mutually exclusive, but some hyperdiploid cases do harbor secondary nonrecurrent translocations involving 14q32. Because they are initiating genetic lesions, hyperdiploidy and *IGH* translocations are detected in both MGUS and MM. The MM subtypes defined by these cytogenetic abnormalities have subsequently been confirmed as distinctive entities through gene expression profiling (GEP) and other genetic analyses.[14,15]

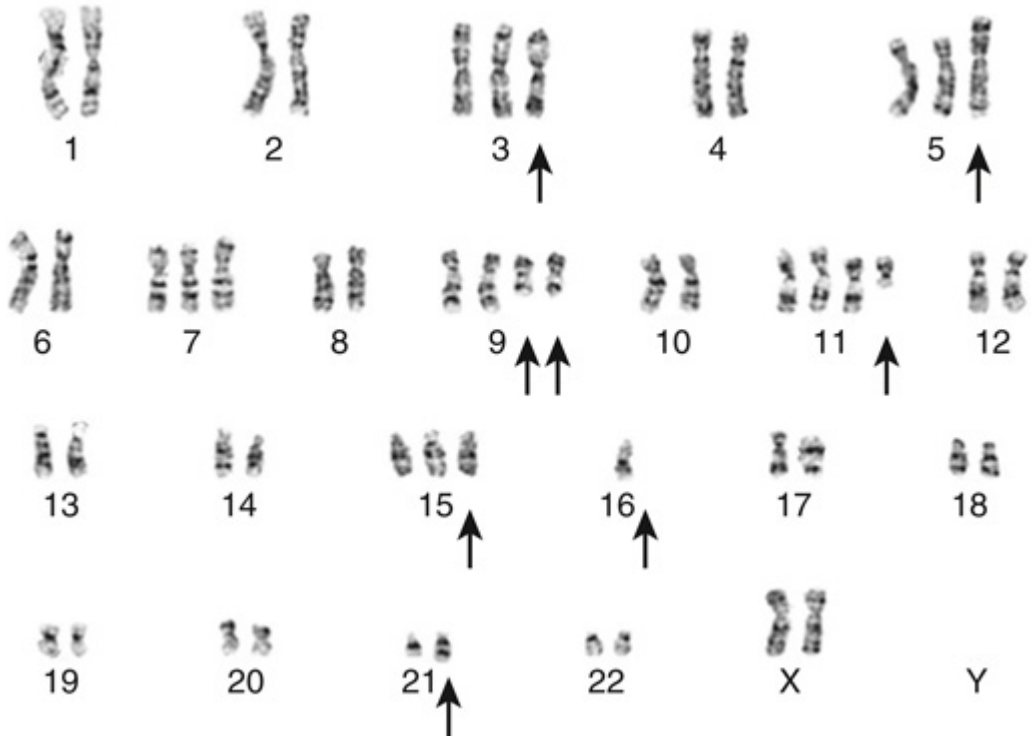

FIGURE 25-1 Metaphase cytogenetic analysis of hyperdiploid multiple myeloma (MM).There are gains of multiple odd-numbered chromosomes (3, 5, 7, 9, 11, and 15), characteristic karyotypic findings in hyperdiploid MM; other abnormalities are present as well, including t(5;9)(p14;q21), +add(11)(q13), and loss of chromosome 16. Courtesy Dr. Teresa Smolarek.

Table 25-1

Overexpression of one of the cyclin D genes *(CCND1, CCND2, CCND3)* is the unifying feature of MM, irrespective of the initiating genetic lesion.[7,8] In MMs harboring the t(11;14), dysregulation is a direct consequence of proximity of *CCND1* to the IGH enhancer,

whereas in other subtypes such as those involving *NSD2/FGFR3* or *MAF* loci, which have a high level of *CCND2* expression, upregulation of cyclin D gene expression is indirect. Hyperdiploid myelomas with trisomy, or less commonly, tetrasomy 11, overexpress *CCND1* or *CCND1* and *CCND2*.

Since the identification of these initiating genetic lesions, major strides have been made toward a more comprehensive understanding of the origin of MM and the genetic basis for disease progression. Several secondary genetic lesions are associated with disease progression, including deletion or mutation of *TP53* (17p13), IGH or Ig light chain (IGL) gene translocations, *MYC* or *MYCN* translocations, chromosome 1p deletion or 1q amplification, inactivation of *CDKN2C* or *RB1,* and activating mutations of *KRAS* or *NRAS*.[16] Some of these mutations, e.g., *TP53* deletion and 1q21 amplification, are incorporated into currently used clinical risk stratification schema.[17,18] Because their presence is indicative of disease progression, most of these genetic lesions are significantly less common in MGUS than in symptomatic MM. For example, *KRAS* and *NRAS* mutations are detected in 30% to 40% of myelomas but only in about 5% of MGUSs.[8,19]

The determinants of disease progression in MGUS or SMM are incompletely understood, and risk of progression is influenced by several factors, including family history, gender, ethnicity, age, and tumor burden. Though the risk for progression of SMM, for example, is typically estimated at approximately 10%, the actual risk for progression is not constant over time.[20] In patients newly diagnosed with SMM, some 50% will progress to symptomatic MM within the first 5 years after diagnosis. The risk of progression drops

significantly thereafter, with only an additional 20% progressing after 5 to 10 years. Significantly, 25% to 30% of patients will never progress to symptomatic MM. MGUS shows similar heterogeneity in its propensity for disease progression.[21]

Various risk stratification models have been developed to identify those individuals at higher risk for disease progression. It is important to remember that these risk stratification models reflect average risk and do not indicate the actual risk for a given patient.[22] In years past, myeloma therapy was toxic and not always associated with significant improvement in survival. However, with the advent of less toxic and more effective therapies, there is now significant interest in assessing whether early therapeutic intervention before the onset of end organ damage results in improved clinical outcomes in patients with SMM, and possibly MGUS. Obviously, such preemptive therapy is predicated on the accurate identification of patients who are at high risk for disease progression. Analyses have demonstrated that significant differences exist between the spectrum and number of mutations in clonal PCs from patients with MGUS and SMM with stable disease and those who ultimately manifest disease progression, with a significantly higher mutation burden in the latter.[22,23] It is important to note that myeloma driver mutations such as *MYC* abnormalities, chromothripsis, templated insertions, and APOBEC activity were detected only in clonal PCs of patients who developed progressive disease. Though such provocative findings need to be confirmed in large, prospective clinical trials, these findings indicate that the early, prospective identification of patients with MGUS/SMM who will develop disease progression is potentially feasible.

Factors involving the bone marrow microenvironment may also play a key role in disease progression. Extracellular matrix proteins, cytokines, growth factors, and the functional consequences of interaction of bone marrow stromal cells with the neoplastic plasma cells all seem to influence the pathophysiology of myeloma.[24]

The mutation spectrum within a patient often shows significant intrapatient heterogeneity. Next-generation sequencing (NGS) analyses of paired aspirate specimens from iliac crest marrow and from focal lesions have shown that, though driver mutations are present in both paired samples, high-risk genetic abnormalities, such as *TP53* mutations or inactivation of *CDKN2C,* are often detected only in focal lesions.[25] These findings suggest that myeloma cells in physically distinct anatomic locations may pursue independent mutational trajectories, likely influenced in part by distinctive aspects of the microenvironment in which these clones evolve. Such findings add further complexity to the genetic analysis of MM and suggest that the standard sampling of routine iliac crest bone marrow may be insufficient for mutation-based prognostication in many patients with myeloma.

Multiple Myeloma

MM is a bone marrow–based, multifocal PCN usually associated with M protein in serum and/or urine.[1,2] The bone marrow is the site of origin of nearly all myelomas, and disseminated marrow involvement is typical. Other organs may be secondarily involved. The diagnosis of MM relies on the integration of clinical, morphologic, immunologic, and radiographic information. The neoplasm spans a clinical spectrum from asymptomatic to highly

aggressive. The pathologic manifestations of the tissue deposition of abnormal Ig molecules are a major clinical finding in a subset of patients with myeloma.[26]

Diagnostic Criteria

The usual findings in MM are increased and abnormal bone marrow PCs or a plasmacytoma together with M protein in serum or urine. Bone lesions are frequently present. The International Myeloma Working Group (IMWG) diagnostic criteria for MM are indicated in **Box 25-3**.[27,28]

Epidemiology

MM (and its variants) is the predominant type of malignant immunosecretory disorder. Myeloma accounts for about 1% of malignant tumors and 10% to 15% of hematopoietic neoplasms.[29] Approximately 35,000 new cases of MM will be diagnosed in the United States in 2022, with an estimated 12,600 disease-related deaths.[30] It is more common in men than women (1.2 to 1) and occurs twice as frequently in African Americans as in Whites.[30] The risk for MM is 3.7-fold higher for individuals with a first-degree relative with the disease.[31] Myeloma is extraordinarily rare in children and is uncommon in adults younger than 35 years; the incidence increases progressively with age thereafter, with approximately 90% of cases occurring in individuals older than 50 years. The median age at diagnosis is 68 to 70 years.[29]

Box 25-3 The International Myeloma Working Group (IMWG) Diagnostic Criteria for Multiple Myeloma

Smoldering Multiple Myeloma (Both Criteria Must Be Satisfied)

1. Serum M protein (IgG or IgA) present at ≥3 gm/dL or urine M protein present at ≥500 mg per 24 hrs, and/or clonal plasma cells (PCs) account for 10% to 60% of bone marrow cells
2. Absence of myeloma-defining events

Multiple Myeloma (Both Criteria Must Be Satisfied)

1. Clonal PCs account for ≥10% of bone marrow cells or biopsy-proven osseous or extraosseous plasmacytoma
2. Myeloma-defining event, ≥1 required
    - End organ damage directly attributable to the clonal PC population, including:
    - Hypercalcemia: serum calcium >0.25 mmol/L (>1 mg/dL) higher than the upper limit of normal or >2.75 mmol/L (>11 mg/dL)
    - Renal insufficiency: creatinine clearance <40 mL/min or serum creatinine >177 μmol/L (>2 mg/dL)
    - Anemia: Hgb at least 2 gm/dL below the lower limit of normal or Hgb <10 g/dL
    - Bone lesions: ≥1 osteolytic lesions identified by skeletal survey, CT, or PET-CT

- Clonal PCs account for ≥60% of bone marrow cells
- Elevated SFLC ratio—involved:uninvolved ≥100, with involved FLC present at ≥100 mg/L
- At least one focal lesion evident by MRI, 5 mm minimum size

Plasma Cell Leukemia

1. Neoplastic PCs morphologically account for ≥5% of leukocytes in patient in whom diagnostic criteria for myeloma are satisfied

Clinical Features

Bone pain in the back or extremities resulting from lytic lesions or osteoporosis is the most common presenting symptom in MM.[28] In advanced cases, vertebral collapse may cause loss of height. Weakness and fatigue, often related to anemia, are common complaints. Some patients present with infections, bleeding, or symptoms related to renal failure or hypercalcemia. Rarely, neurologic manifestations caused by spinal cord compression or peripheral neuropathy are the reason for seeking medical attention.[28] MM is occasionally diagnosed in asymptomatic individuals in whom serum M protein is incidentally detected during evaluation for an unrelated medical condition. These patients often present with elevated total protein levels, which upon further investigation are the result of an M spike.

Physical findings are often non-specific or lacking. Pallor is most common, followed by organomegaly. Palpable plasmacytomas are

rare, but tenderness and swelling over the site of a pathologic fracture or plasmacytoma may be encountered. Tissue masses and organomegaly caused by PC infiltration or amyloidosis are occasionally encountered. Skin lesions caused by PC infiltrates or purpura are observed in rare cases.[28]

Laboratory Findings

The diagnostic studies recommended by the IMWG for the evaluation of suspected MM are indicated in **Box 25-4**.[28,32,33] The data obtained from these studies form the basis for clinicopathologic criteria for diagnosis of MM and provide important prognostic information.

Box 25-4 Diagnostic Studies for Multiple Myeloma

- History and physical examination
- Complete blood count and leukocyte differential count
- Peripheral blood smear examination
- Chemistry screen, including calcium, creatinine β_2 microglobulin
- C-reactive protein, lactate dehydrogenase
- Nephelometric or immunoturbidimetric quantification of immunoglobulins
- Serum protein electrophoresis and immunofixation
- Serum free light chain quantitation
- Urinalysis

- 24-hour urine collection for electrophoresis and immunofixation
- Bone marrow examination, including:
  - Aspirate and trephine biopsy
  - Genetic studies, including metaphase cytogenetics and fluorescence in situ hybridization (FISH)
  - Immunophenotyping
  - Plasma cell labeling index
- Imaging studies: radiologic skeletal survey at a minimum; low-dose CT or FDG PET-CT preferred

Assessment of serum and urine for M protein is an essential component of the diagnostic workup of a patient with suspected MM. Capillary electrophoresis is the most commonly used methodology. M protein is evident by serum protein electrophoresis (SPE) in most patients with myeloma, although the sensitivity of detection of monoclonal free light chains (FLCs) by SPE is low (**Fig. 25-2**).[34] The total Ig is usually increased as a result of the M protein. However, normal polyclonal Igs are commonly decreased, and absolute hypogammaglobulinemia may be present because of the suppressed synthesis of normal serum Ig, or immunoparesis, that is common in myeloma.[29] M protein may be undetectable by SPE in cases with low levels of monoclonal Ig, as is common in IgD, IgE, and light chain (LC) myeloma; hypogammaglobulinemia may be the only abnormal SPE finding in such cases. Urine protein electrophoresis (UPE) performed on a concentrated urine specimen and Ig quantification on a 24-hour urine collection should also be obtained (**Fig. 25-3**). A monoclonal LC (Bence-Jones protein) is found in some patients without serum M protein. Serum and urine immunofixation

electrophoresis (IFE) is the gold standard for the characterization of HCs and LCs and for detecting low-quantity M protein, as may be seen in patients with LC amyloidosis, plasmacytoma, and after treatment for myeloma (Figs. **25-2** and **25-3**). IFE can detect an M protein level of 0.02 g/dL in serum and 0.004 g/dL in urine.[32] M protein is identified in the serum or urine by IFE in about 97% of myeloma cases.[29,32] Monoclonal LCs are detected in the urine in 75% of cases, the majority of which are kappa type. The presence of detectable urinary LC is a reflection, in part, of the patient's renal function, as LCs are reabsorbed in the proximal renal tubule.

The serum FLC (SFLC) immunoassay provides a highly sensitive method for detecting very small quantities of monoclonal LCs and is more sensitive than IFE.[35] The SFLC quantity and the kappa-to-lambda ratio are powerful determinants of disease activity.[36] SFLC analysis is important in screening and monitoring patients with PCNs, especially oligosecretory ones such as some LC-chain-only myelomas, amyloidosis, solitary plasmacytoma, and a majority of those previously considered nonsecretory myeloma.[36-38] The baseline SFLC quantity and ratio are important indicators of prognosis for every category of PCN, including MGUS.[37] A normal SFLC ratio is a criterion of stringent complete response for treated PCNs, together with absence of M protein by IFE and absence of clonal PC in the bone marrow.[38] FLCs exist as monomers, dimers, and oligomers, with lambda FLC having a particular propensity to form higher-order complexes. Currently, several SFLC assays are commercially available, each of which uses different assay methodologies and unique antibodies for FLC detection that differ in their capacity to recognize monomeric versus dimeric forms of the

FLCs.[39,40] As such, these SFLC platforms are not harmonized. Therefore, initial and subsequent clinical monitoring of SFLC levels in a given patient should be performed using the same SFLC analytic platform.[39,41]

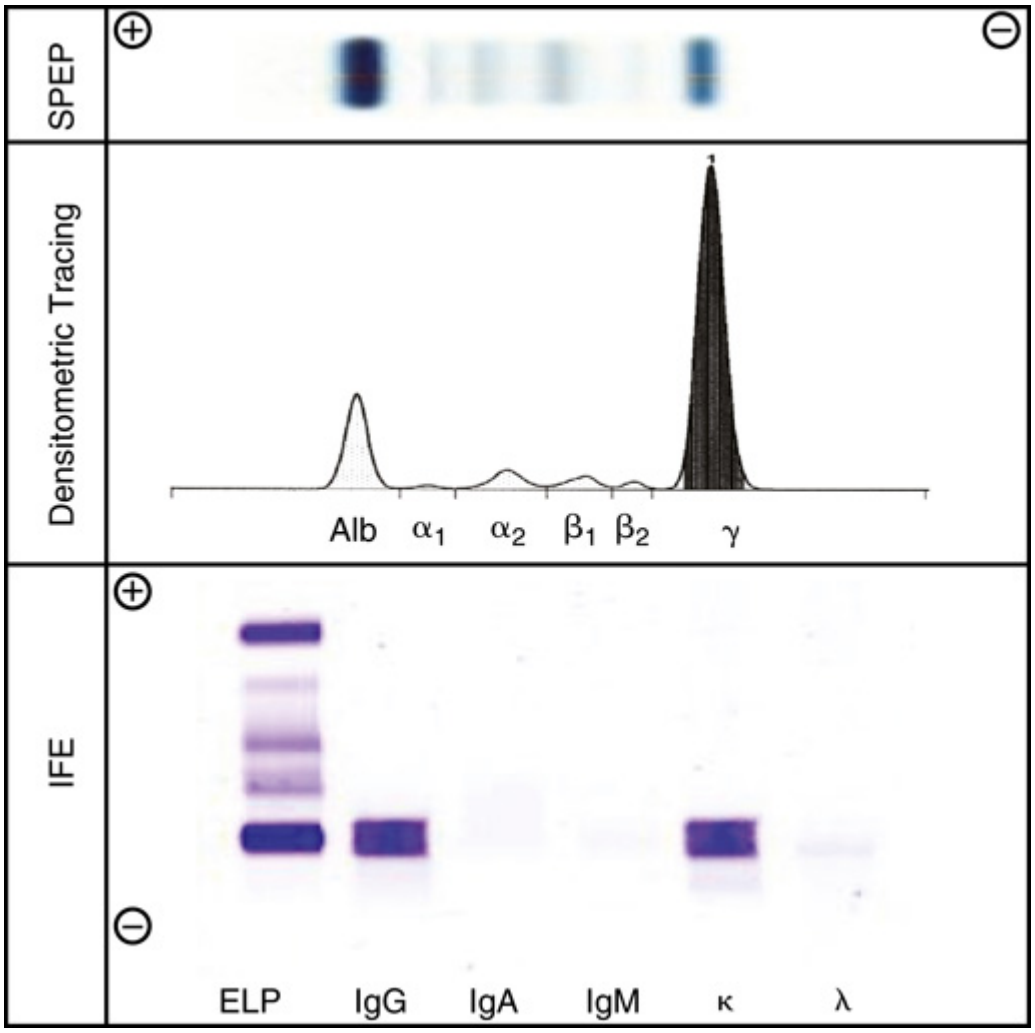

FIGURE 25-2 Serum electrophoreses study in multiple myeloma (MM).A single, large (8.1 g/dL) M-protein peak (shaded area 1 on densitometric tracing in middle panel) is detected by serum protein electrophoresis located in the γ region of the electrophoretogram. M protein is identified by immunofixation electrophoresis (IFE) as IgG kappa. Courtesy Drs. Frank H. Wians Jr. and Dennis C. Wooten.

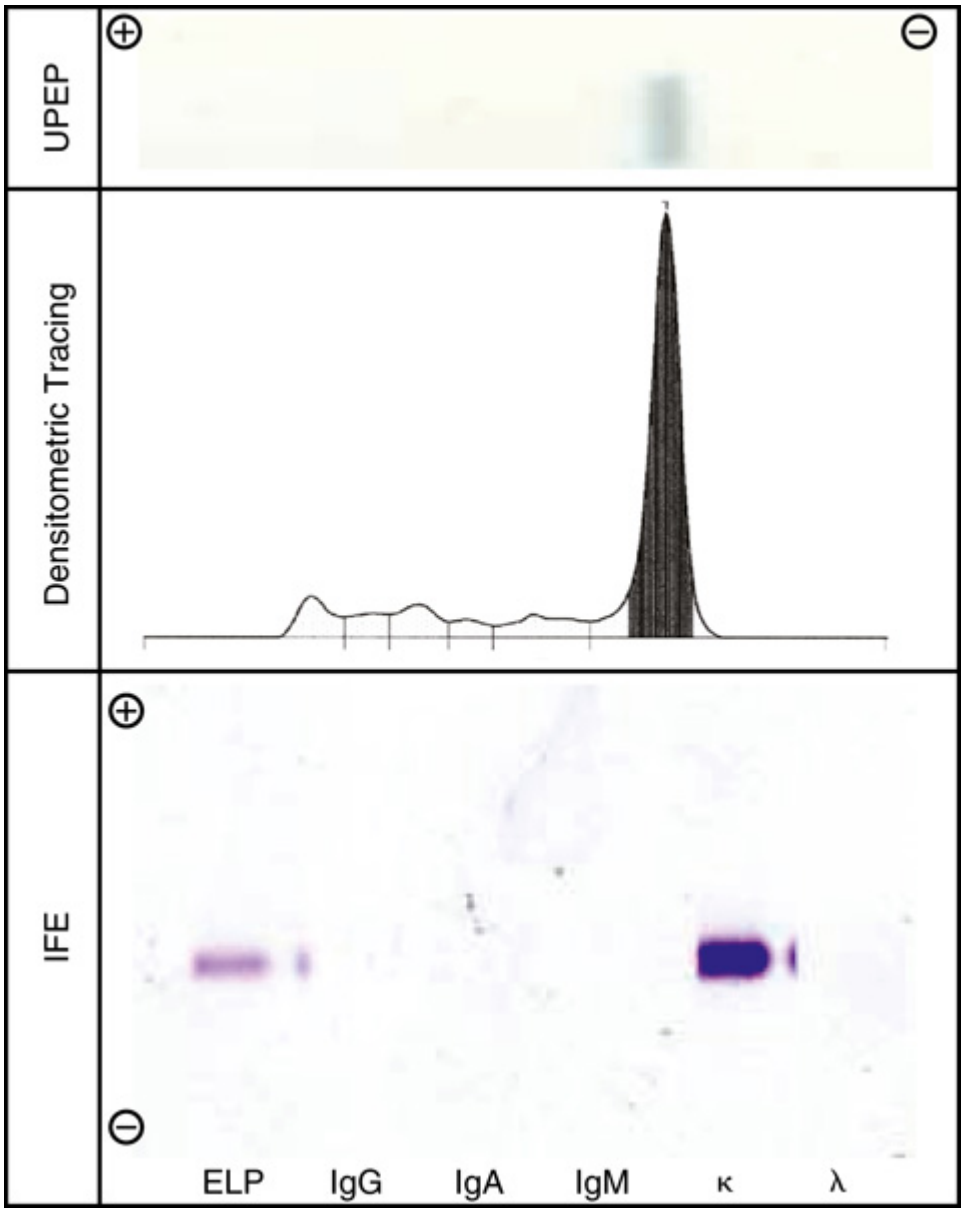

FIGURE 25-3 Urine protein electrophoreses in light-chain-only multiple myeloma (MM).Analysis of a concentrated 24-hour urine specimen demonstrated a single M-protein peak (140 mg/24 hr) *(shaded area 1 on densitometric tracing in middle panel)* in the γ region of the gel. M protein is identified by immunofixation electrophoresis (IFE) as free kappa light chain.

No M protein is detected by serum protein electrophoresis. Courtesy Drs. Frank H. Wians Jr. and Dennis C. Wooten.

An IgG is the most common M protein in myeloma and is detected in about 50% of cases, followed by IgA and monoclonal LC only, each present in approximately 20% of cases.[29] IgD, IgE, IgM, or biclonal M protein is present in the remaining 5% to 10% of cases. Nonsecretory myeloma, as assessed by IFE, accounts for less than 3% of cases; however, low quantities of monoclonal LC are detectable in most of these "nonsecretory" cases by SFLC analysis.[37,42] Kappa LC is more common than lambda LC for all Ig types of myeloma except IgD.[43-45] The quantity of serum M protein varies considerably from undetectable to more than 10 g/dL, with median levels of approximately 5 g/dL for IgG myeloma and 3.5 g/dL for IgA. Approximately 40% of patients with symptomatic myeloma have an M protein level less than 3 g/dL.[32] The serum M protein level may be very low or undetectable in cases of LC-only myeloma; the 24-hour urine protein is usually mildly-to-markedly elevated.

Anemia is present at diagnosis in about two-thirds of patients.[29,32] Red blood cell indices are usually normocytic and normochromic. Leukopenia and thrombocytopenia are found in less than 20% of patients but frequently worsen as the disease progresses.[29] Leukocytosis or thrombocytosis is occasionally present. The erythrocyte sedimentation rate is variably increased and roughly related to the level of M protein.

Hypercalcemia is present in approximately 20% of patients, and creatinine is elevated in 20% to 35%.[32] Hyperuricemia is detected in

over 50% of patients.[29,32] Hypoalbuminemia is observed in patients with advanced disease.

Genetic Studies

Conventional karyotyping was the standard for detecting genomic abnormalities and outcome discrimination in MM for many years. This technique remains an important component of genetic assessment but has a relatively low sensitivity. Only 30% to 40% of MMs have identifiable abnormalities by karyotype analysis, due in part to the low in vitro proliferation and lack of analyzable metaphases of many myelomas and the cryptic nature of several common chromosomal rearrangements. Despite its relatively low sensitivity, conventional cytogenetic analysis should be performed at diagnosis of MM. Conventional karyotyping readily detects several complex abnormalities in MM, some of which would not be identified by fluorescence in situ hybridization (FISH) studies. For example, patients with important prognostic karyotypic changes, such as hypodiploidy, may not have FISH-defined risk abnormalities.

Box 25-5 Recommended Genetic Studies for Multiple Myeloma

Fluorescence in situ hybridization (FISH) should be performed on enriched plasma cell (PC) fraction (most commonly used) or combined with cyIg staining.

Minimal FISH Panel:

- t(4;14)(p16;q32)

- t(14;16)(q32;q23)
- del(17p13) *[TP53]*
- chromosome 1 abnormalities (1q21 gain and 1p32 deletion)
- odd numbered chromosomes

Expanded FISH Panel:

- t(11;14)(q13;q32)
- del(13)

Include gene expression profiling (GEP) data for risk stratification/prognostication in clinical trials.

FISH contributes significantly to current risk stratification models for MM, and as such, should be performed in all cases at initial diagnosis (**Box 25-5**).[17,18,46] Because it does not depend on the in vitro proliferation of neoplastic PCs, myeloma-associated genetic alterations are readily detected by interphase FISH in more than 90% of cases. FISH also detects important cryptic genetic abnormalities, such as the t(4:14)(p16;q32) *NSD2*::*IGH*, that are undetectable by conventional karyotyping. An important technical caveat on FISH analysis is that the PC percentage in a bone marrow specimen may be below the sensitivity threshold of most FISH assays, particularly in MGUS or SMM. In such cases, FISH should be performed on samples in which the PCs have been enriched by either CD138 magnetic bead purification or flow cytometry-based cell sorting or stained for cytoplasmic Ig.[47,48]

Although gene expression profiling and other NGS-based analytic techniques with prognostic discrimination have been reported, most are not widely used in the clinical setting.

Several risk stratification schemes have been published.[46] The revised International Staging System (R-ISS) and that of the IMWG are widely used clinically (Tables **25-2** and **25-3**).[17,18,46] Risk stratification in both the R-ISS and IMWG is based in part on the findings of FISH studies.[17,18]

Radiographic Studies

Radiographic skeletal surveys reveal lytic lesions, osteoporosis, or fractures in 70% to 85% of cases of myeloma at diagnosis, all of which are present in some patients.[29,32,49] The vertebrae, pelvis, skull, ribs, femur, and proximal humerus are most often affected.[50]

Computed tomography (CT) and other imaging modalities are more sensitive than the conventional skeletal survey and can detect small osteolytic lesions in areas not well visualized by conventional techniques.[33,50] Consequently, low-dose whole-body CT or FDG positron emission tomography-CT (PET-CT) is now recommended in the diagnostic workup of suspected MM whenever possible.[33] PET-CT is superior in detection of the extent of myelomatous involvement, including soft-tissue disease.[50] The presence of multiple osseous focal lesions or extramedullary disease by PET-CT and magnetic resonance imaging (MRI) has adverse prognostic significance in patients with symptomatic myeloma.[51-53]

Table 25-2

The International Myeloma Working Group (IMWG) Risk Stratification of Multiple Myeloma

Low Risk (50%)	Intermediate Risk (30%)	High Risk (20%)
ISS I/II	ISS III with no adverse FISH*	ISS II/III
No adverse FISH*	ISS I and adverse FISH*	Adverse FISH*
OS: 76% at 4 years	OS: 45% at 4 years	OS: 33% at 4 years

FISH, Fluorescence in situ hybridization; *ISS,* International Staging System; *OS,* overall survival.

* Adverse FISH includes the presence of either the t(4;14) or 17p13 *(TP53)* deletion.

Table 25-3

Revised International Staging System for Multiple Myeloma

R-ISS Stage I	R-ISS Stage II	R-ISS Stage III
ISS I **Normal LDH**	Not R-ISS stage I or III	ISS III
Standard risk CA by FISH*		High-risk CA by FISH, or High LDH
OS: 82% at 5 years	OS: 62% at 5 years	OS: 40% at 5 years

CA, Chromosomal abnormalities; *FISH,* fluorescence in situ hybridization; *OS,* overall survival; *R-ISS,* revised International Staging System.

* High-risk CA defined as the presence of either the t(4;14), t(14;16), or 17p13 *(TP53)* deletion

Blood Findings

Rouleaux formation is usually the most striking feature on blood smears and is related to the quantity and type of M protein (**Fig. 25-4**). Circulating nucleated red cells or a leukoerythroblastic reaction is present in some cases. PCs are found on blood smears in approximately 15% of cases, usually in small numbers. They are more commonly observed in the advanced stages of disease. Cases in

which there is significant plasmacytosis may satisfy diagnostic criteria for plasma cell leukemia (discussed subsequently).

Bone Marrow Morphologic Findings

Bone marrow examination is the most important component of the diagnostic workup of MM and is nearly always required to confirm the diagnosis, even when there is substantial clinical, laboratory, and radiographic evidence to suggest a diagnosis of myeloma. Bone marrow evaluation also provides prognostic information and is useful in evaluating the response to therapy or identifying recurrent disease. Because they have complementary roles in the diagnostic workup, both a bone marrow aspirate and biopsy should be obtained if possible.

The bone marrow aspirate affords optimal evaluation of the cytologic features of the neoplastic cells and provides material for flow cytometric, cytogenetic, and molecular studies. The frequency of neoplastic PCs in the bone marrow aspirate smear is widely variable but averages about 20% to 36%.[29,54] PCs account for less than 10% of the marrow cellularity in about 5% of cases of symptomatic myeloma, which likely reflects the patchy marrow involvement that is common in MM.[32,54] An extreme example of this is so-called macrofocal myeloma in which the bulk of the neoplastic PCs reside within focal lesions with only low-level disease present in the intervening bone marrow, including that typically sampled by random marrow aspiration and biopsy.[55,56]

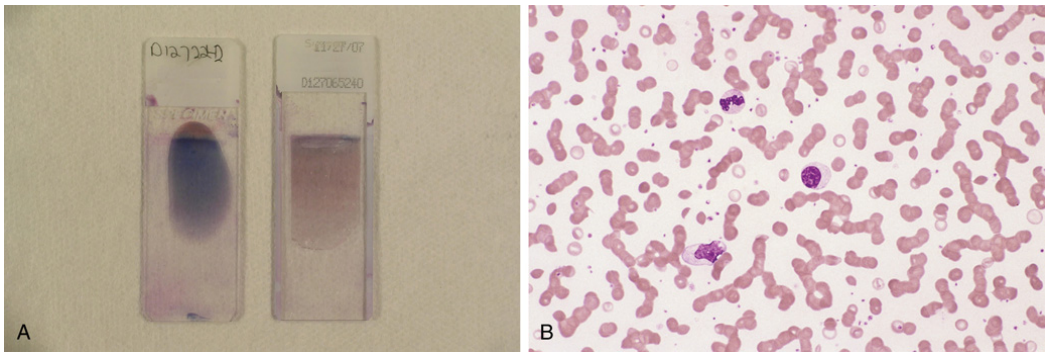

FIGURE 25-4 Blood smear findings in multiple myeloma (MM).**A,** The smear shown on the *left* is from a patient with myeloma with a large M-spike *(a normal smear is shown on the right for comparison)*. The smear has a distinctly violaceous hue from the paraproteinemia and an abnormal oval shape reflecting altered spreading of red blood cells during slide preparation because of the presence of rouleaux. **B,** There is prominent rouleaux formation in this blood smear from a patient with a high M-protein level. Although rouleaux are an important diagnostic clue to an underlying plasma cell neoplasm (PCN), they may be present in other conditions, including inflammatory states (Wright-Giemsa stain).

The biopsy usually provides a more accurate assessment of the extent of myelomatous marrow involvement. This is particularly true for myelomas with associated reticulin or collagen fibrosis, as neoplastic PCs are grossly underrepresented in the aspirate smear in such cases. Myelofibrosis is present in approximately 10% of cases,

may be extensive, and is associated with diffuse bone marrow involvement and aggressive disease in some studies.[54,57-59] A disproportionately high number of myelofibrotic myelomas produce monoclonal LCs only.[57] Bone marrow biopsies are also useful in post-therapy evaluation, as persistent myelomatous deposits may have significant associated fibrosis. In addition, amyloid deposits and other considerations in the clinical differential diagnosis of MM, such as metastatic carcinoma or disseminated Hodgkin lymphoma, are optimally evaluated in the bone marrow biopsy.

Neoplastic myeloma cells show overt evidence of plasmacytic differentiation in most cases and do not usually pose a diagnostic challenge. Though neoplastic PCs may sometimes closely resemble their benign counterparts (**Fig. 25-5**), they often manifest one or more cytologic abnormalities. Benign PCs are small and contain single nuclei with smooth, round contours, peripherally clumped chromatin, and indistinct nucleoli. By contrast, neoplastic myeloma cells are often larger than benign PCs. The chromatin may be less condensed in some myelomas, and there may be distinct or prominent nucleoli (**Figs. 25-6 to 25-9**). Nuclear abnormalities may also be present, including nuclear lobation and convolution (**Fig. 25-10**).[54,60] In some cases, these cells are mixed with other easily recognizable PCs, but in other cases they make up a relatively uniform population and may be difficult to recognize as myeloma cells (**Fig. 25-10**).

Myelomas with atypical PC morphology may be difficult to recognize as such in bone marrow biopsies (**Figs. 25-11 to 25-13**). Myelomas with plasmablastic, lymphoplasmacytic, or anaplastic morphology are particularly problematic. Cytologic examination of

the cells in the aspirate smears and immunohistochemistry (IHC) may be essential for diagnosis in these cases.

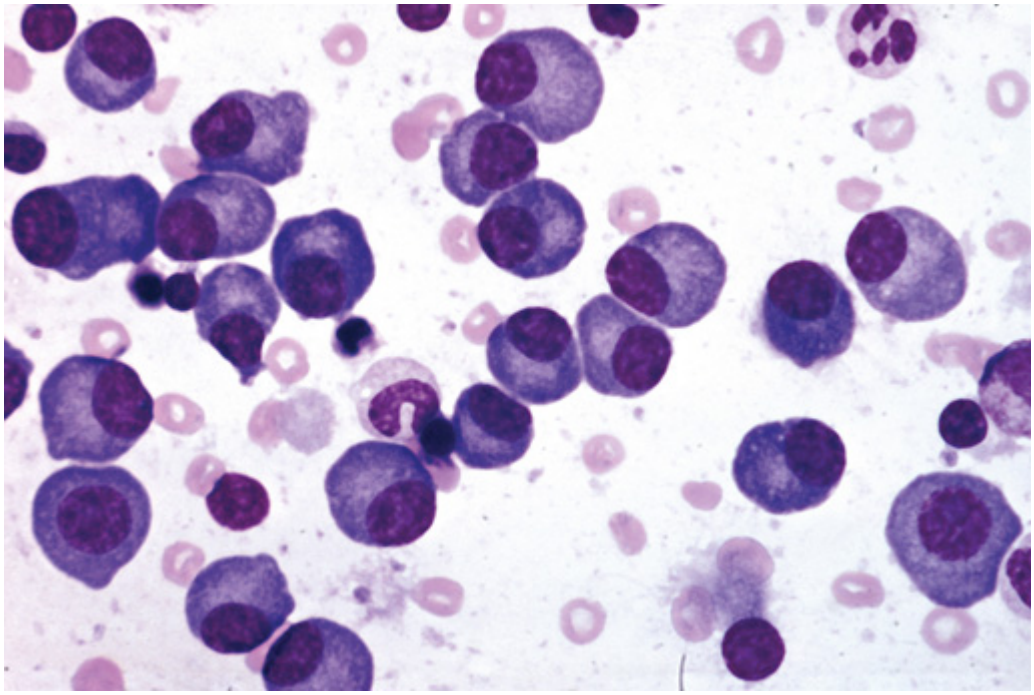

FIGURE 25-5 Mature-type myeloma.In this case, the myeloma cells have cytologic features approximating those of mature PCs (bone marrow aspirate; Wright-Giemsa stain). Courtesy Dr. Patrick C.J. Ward.

Myelomas with so-called lymphoplasmacytic morphology may be especially challenging because of their morphologic similarity to mature B-cell neoplasms such as chronic lymphocytic leukemia (CLL). In this variant, which accounts for about 5% of myelomas, the neoplastic PCs have relatively scant cytoplasm and may resemble the mature lymphocytes of CLL and low-grade lymphomas with plasmacytic differentiation (**Fig. 25-14**). These myelomas usually

harbor t(11;14) and frequently co-express CD20 and other B-lineage antigens, including PAX5.[61-64] Positivity for CD138 and cyclin D1 by IHC readily distinguishes lymphoplasmacytic myeloma from these other low-grade B-cell lymphomas. Flow cytometry is also useful, as the myeloma cells usually lack CD19 and often express CD56, which is not seen in other B-cell lymphomas.

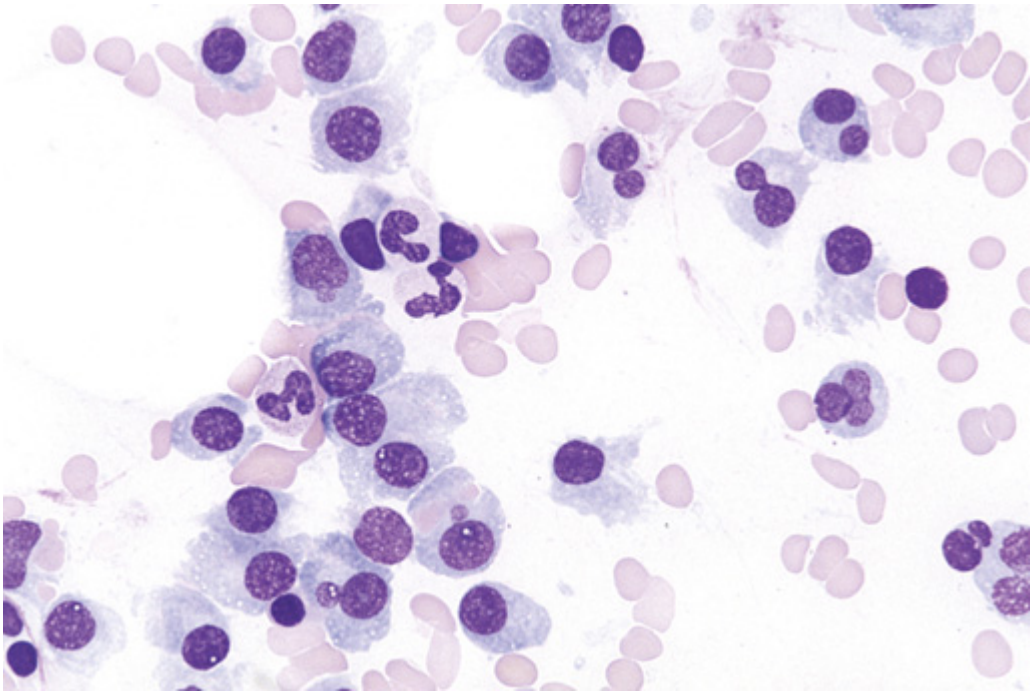

FIGURE 25-6 Intermediate-type myeloma.The neoplastic plasma cells exhibit features intermediate between mature and immature types of myeloma. They have moderately dispersed chromatin and occasional small nucleoli; several have lobated nuclei, and two are binucleate (bone marrow aspirate; Wright-Giemsa stain).

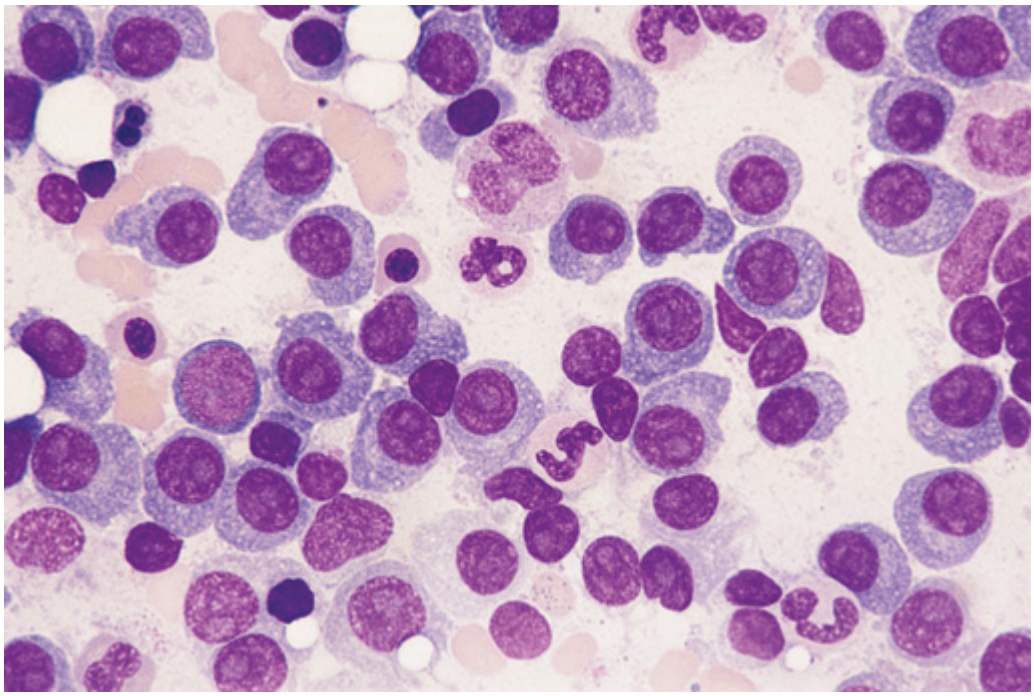

FIGURE 25-7 Immature-type myeloma.The neoplastic plasma cells contain prominent nucleoli and more dispersed chromatin than those in Figure 25-6. The marrow is extensively replaced with myeloma (bone marrow aspirate; Wright-Giemsa stain).

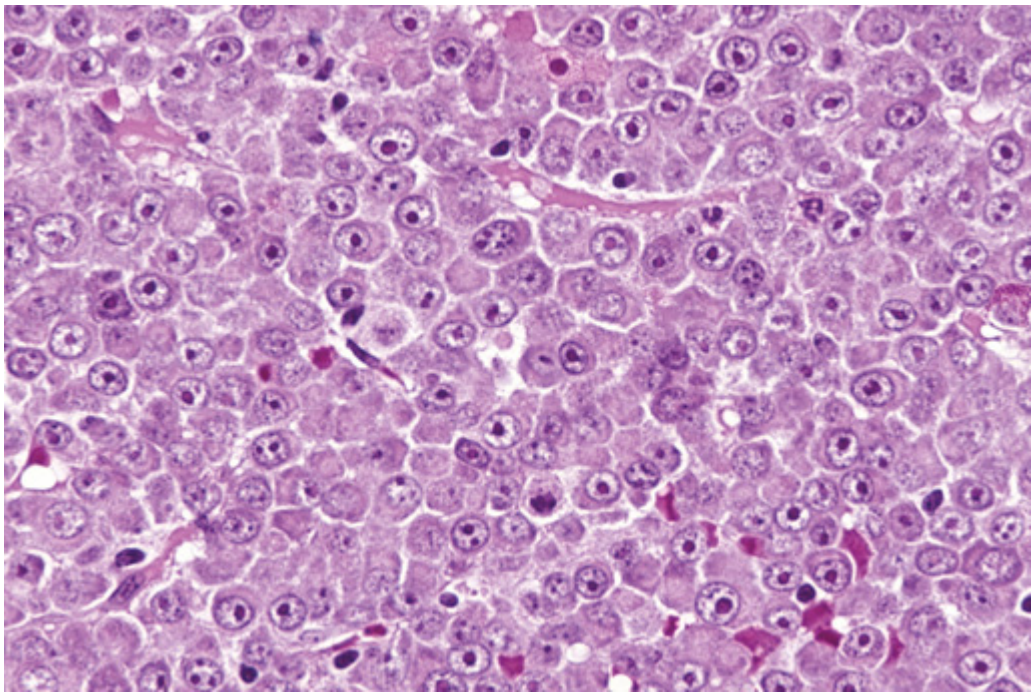

FIGURE 25-8 Immature-type multiple myeloma (MM).In this case, the myeloma cells are large and contain vesicular nuclei, prominent eosinophilic nucleoli, and a moderate amount of eosinophilic cytoplasm. The corresponding bone marrow aspirate smear is shown in Figure 25-7 (bone marrow biopsy; H&E stain).

Various grading schemes have been proposed based on the morphologic features of the neoplastic PCs or frequency of plasmablasts in either the biopsy or aspirate, some of which were predictive of clinical outcome.[59,65-67] All of these were developed 30 to 40 years ago, and it is uncertain whether they retain any prognostic relevance with the advent of novel antimyeloma chemotherapeutics. Though myeloma grading is not mandated in the ICC, it is appropriate to make note of the presence of high-grade cytologic features in the clinical hematopathology report.

The degree of bone marrow involvement in myeloma is best assessed in the bone marrow biopsy. The pattern of the PC infiltrate may be interstitial, focal, or diffuse, and the extent of marrow involvement varies from an apparently small increase in PCs to complete replacement (**Fig. 25-15**).[54,59] The pattern of marrow involvement is usually directly related to the overall burden of neoplastic PCs. There is often considerable marrow sparing and preservation of normal hematopoiesis with interstitial and focal involvement. By contrast, diffuse involvement results in extensive replacement of the marrow and suppression of normal hematopoiesis, which may manifest as cytopenias in the complete blood count. Osteolytic lesions may develop in areas of diffuse myelomatous involvement (**Fig. 25-16**). There is typically progression from interstitial and focal disease in early myeloma to diffuse involvement in advanced stages of the disease.[59]

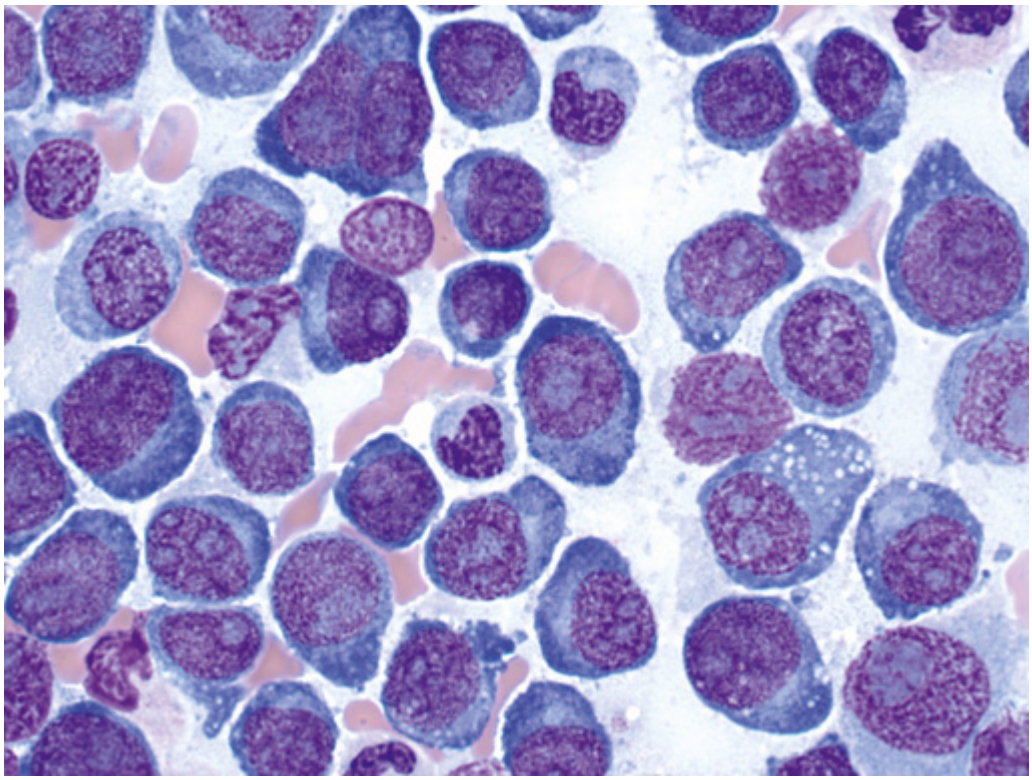

FIGURE 25-9 Myeloma with high-grade cytologic features.The neoplastic cells in this case are large with dispersed chromatin. Many contain prominent nucleoli and relatively scant cytoplasm, cytologic features of plasmablasts (Wright-Giemsa stain).

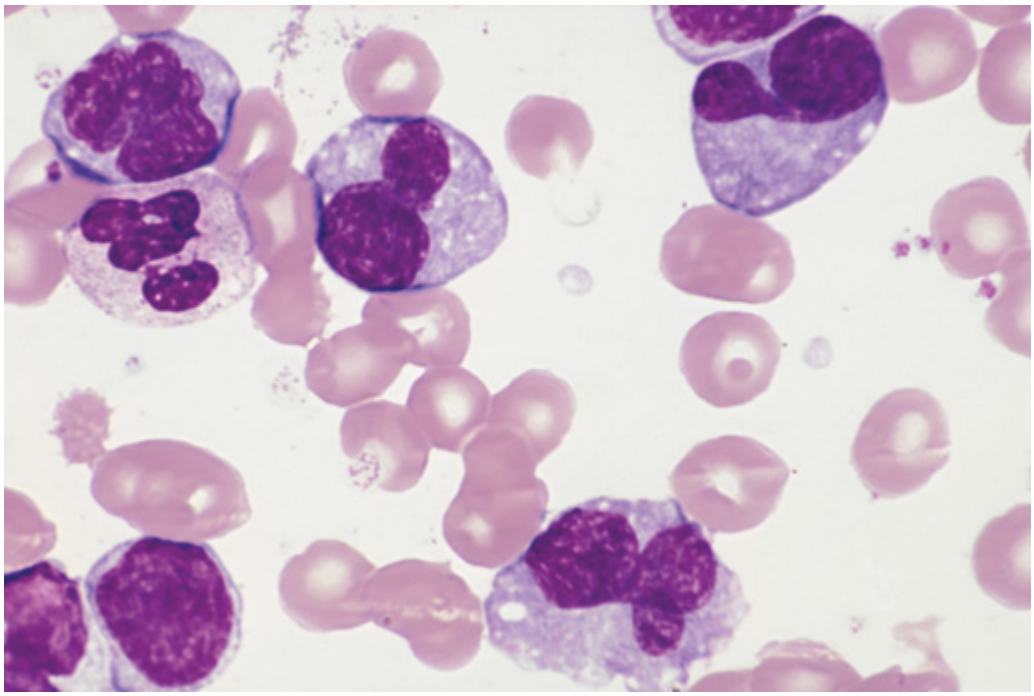

FIGURE 25-10 Myeloma with nuclear lobulation.Most of the neoplastic plasma cells (PCs) in this case show striking nuclear irregularity and convolution. The neoplastic cells in myelomas of this type may be difficult to recognize as PCs (bone marrow aspirate; Wright-Giemsa stain).

Myeloma cells may manifest one of several peculiar nuclear and cytoplasmic findings that result mostly from either the synthesis of an abnormal Ig molecule or perturbation of Ig secretion. Many of these are best appreciated in the aspirate smear. Dutcher bodies are occasionally encountered, most commonly in IgA myelomas, where they are present in about 20% of cases.[54] These are pale staining, single, and generally large nuclear pseudoinclusions that result from cytoplasmic invagination into the nucleus (**Fig. 25-17**).

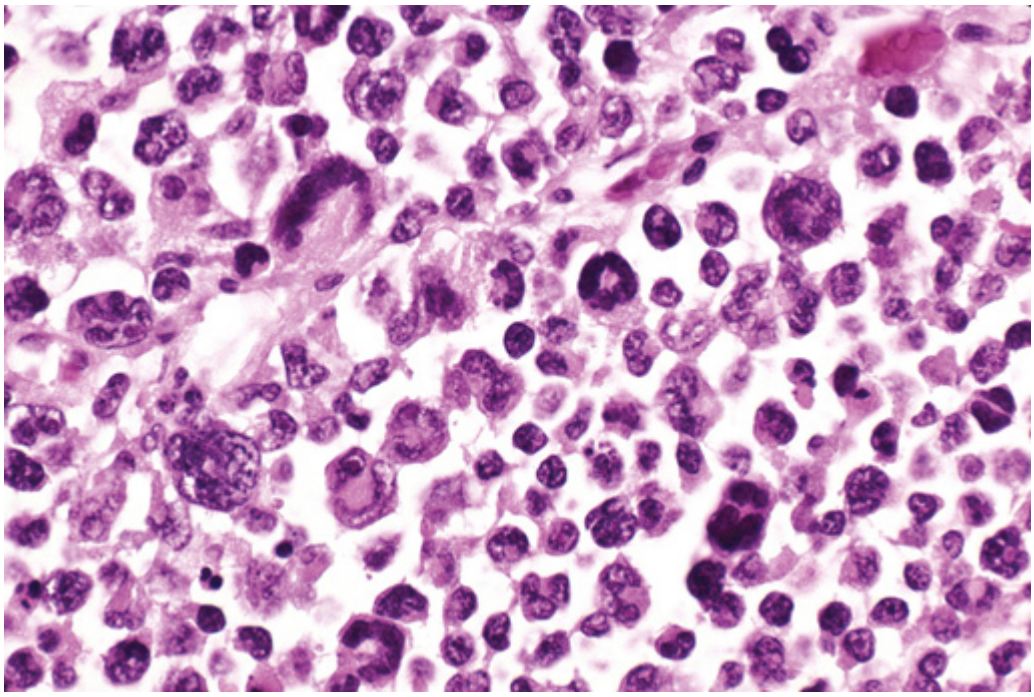

FIGURE 25-11 Poorly differentiated myeloma with anaplastic cells.A dense infiltrate of anaplastic neoplastic cells is present, most of which lack obvious plasmacytic differentiation. The cells were positive for CD138 kappa light chain restriction by immunohistochemistry. This type of myeloma must be differentiated from anaplastic large cell lymphoma and metastatic tumors such as anaplastic carcinoma and melanoma (bone marrow biopsy; H&E stain). Courtesy Dr. Patrick C.J. Ward.

Cytoplasmic vacuoles are commonly encountered in myeloma. The size and frequency of the vacuoles is quite variable. In some cases, single large vacuoles in myeloma cells peripherally displace the nucleus, imparting a signet ring cell appearance that may resemble that of a metastatic gastrointestinal carcinoma (**Fig. 25-18**).

Cytoplasmic inclusions are also encountered, the most common of which are Russell bodies (**Fig. 25-18**). In some cases, cytoplasmic inclusions are present that impart a Gaucher cell-like appearance to the neoplastic PCs (**Fig. 25-19**). Myelomas containing rhomboid or needle-like cytoplasmic crystals are rare and are predominantly kappa-LC restricted (Figs. **25-20** and **25-21**). The neoplastic PCs may resemble promyelocytes when needle-like inclusions are abundant (**Fig. 25-21**). Inclusions may also be present in proximal tubular cells in the kidney and are associated with Fanconi syndrome.[68] Cytoplasmic crystals within clonal neoplastic PCs can be associated with corneal disease and have rarely been reported in a case of polychromatic crystalline keratopathy.[69] Crystal storing histiocytosis (CSH) is a rare reactive proliferation that may develop in association with crystal-containing myelomas and occasionally other lymphomas showing plasmacytic differentiation.[70-72] This histiocytic proliferation may be florid in some cases and obscure the underlying myeloma (**Fig. 25-22**). The histiocytes in CSH bear some resemblance to those of storage disorders such as Gaucher disease, although the refractile quality of the crystals in CSH is distinctive. PCs with pale, frayed, and fragmented cytoplasm and so-called flaming PCs are more common in IgA myeloma (**Fig. 25-23**). Finally, phagocytic PCs may rarely be present in myeloma.[73,74]

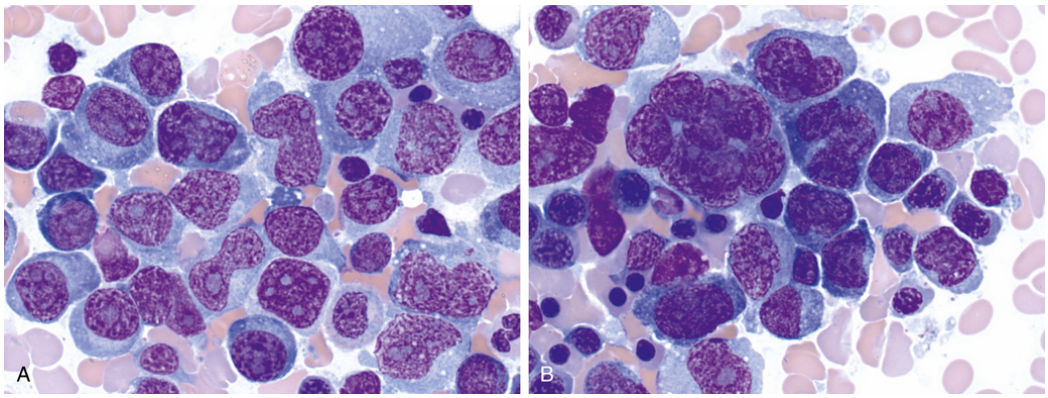

FIGURE 25-12 Poorly differentiated myeloma with anaplastic cells.**A** and **B,** As in Figure 25-11, frequent anaplastic cells are present. The plasmacytic features of the neoplastic cells in such cases are often more apparent in the aspirate than in the biopsy. Anaplastic myeloma cells should be distinguished from megakaryocytes and other malignancies (bone marrow aspirate; Wright-Giemsa stain).

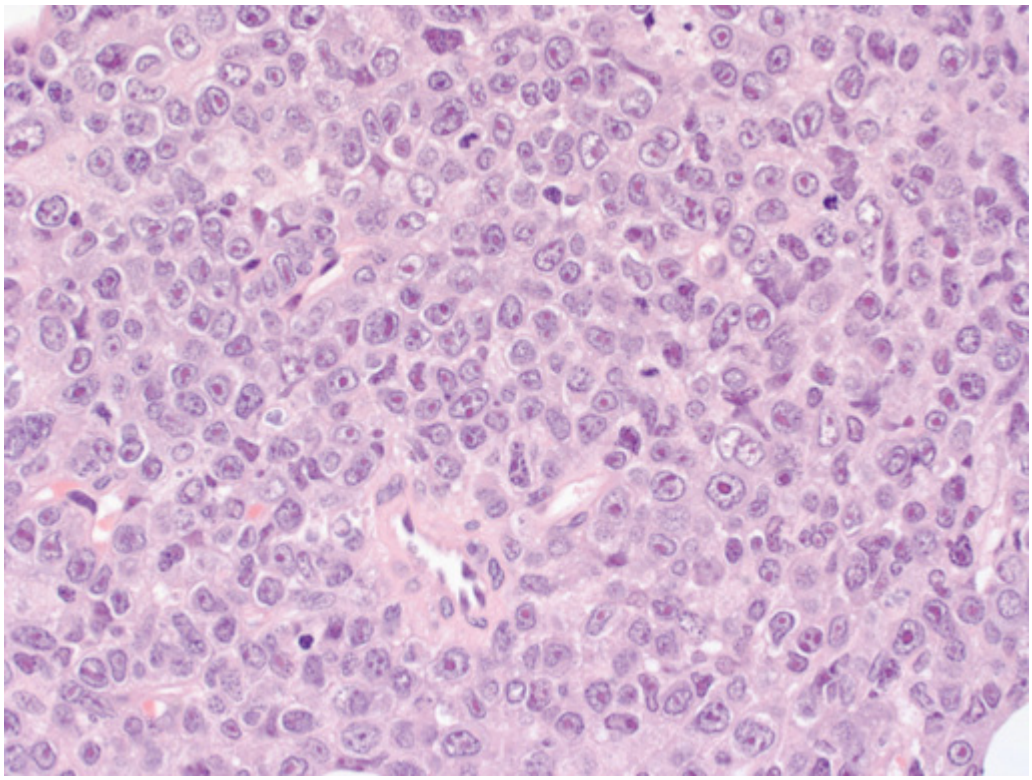

FIGURE 25-13 Plasmablastic-type multiple myeloma.There is heavy interstitial involvement with myeloma. The neoplastic plasma cells are poorly differentiated with a high nuclear-to-cytoplasmic ratio, dispersed chromatin, and prominent nucleoli. Such high-grade cytologic features raise a differential diagnosis that includes large cell lymphoma and small blue-cell tumors.

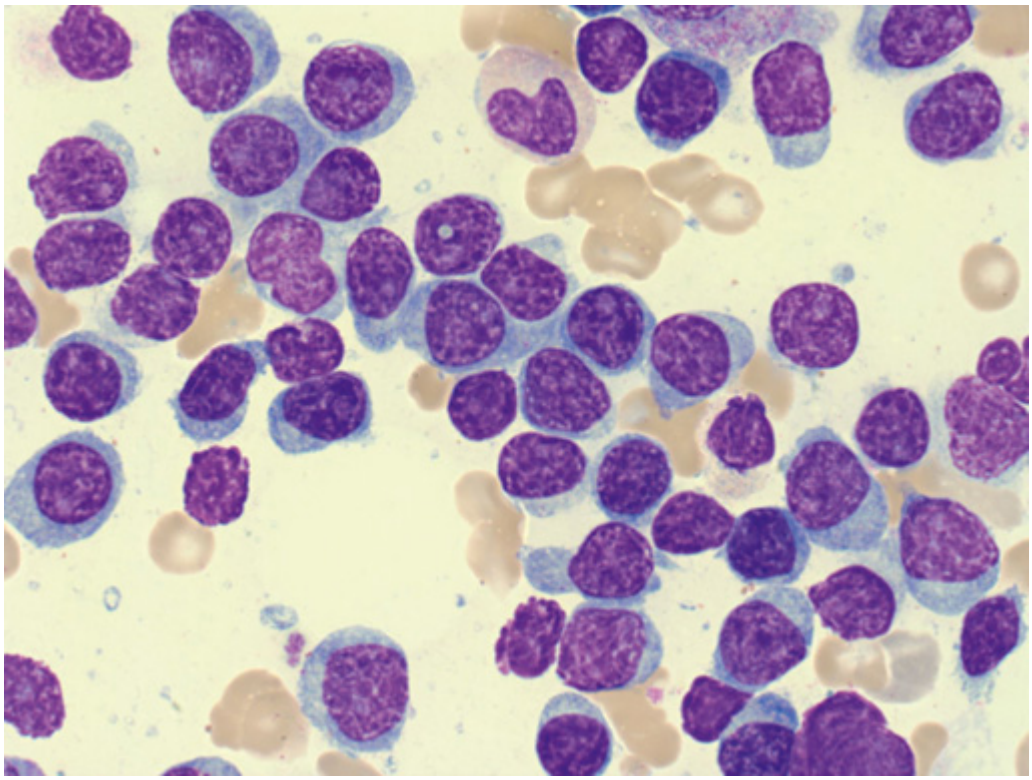

FIGURE 25-14 Small lymphocyte-like myeloma.The neoplastic plasma cells contain more scant cytoplasm than is typical of most myelomas, cytologically resembling plasmacytoid lymphocytes (bone marrow aspirate; Wright-Giemsa stain).

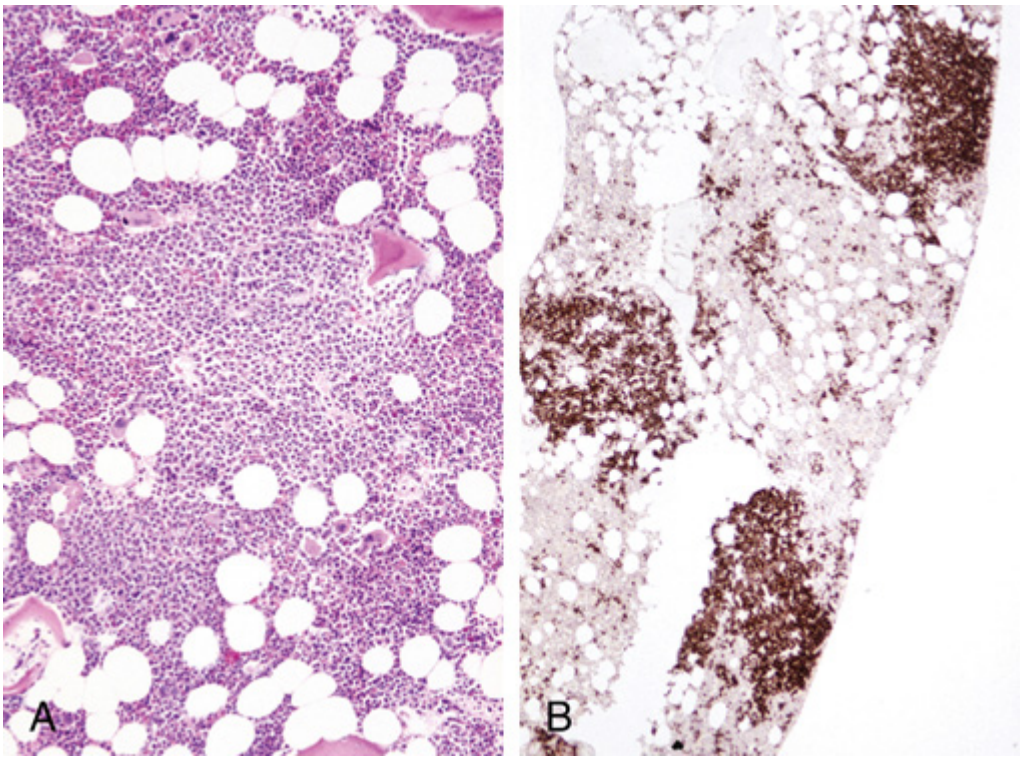

FIGURE 25-15 Focal bone marrow involvement by myeloma.**A,** Focal myeloma infiltrates are scattered throughout the bone marrow with mostly normal intervening hematopoietic tissue (H&E stain). **B,** Lambda light chain immunohistochemistry highlights the predominantly focal pattern.

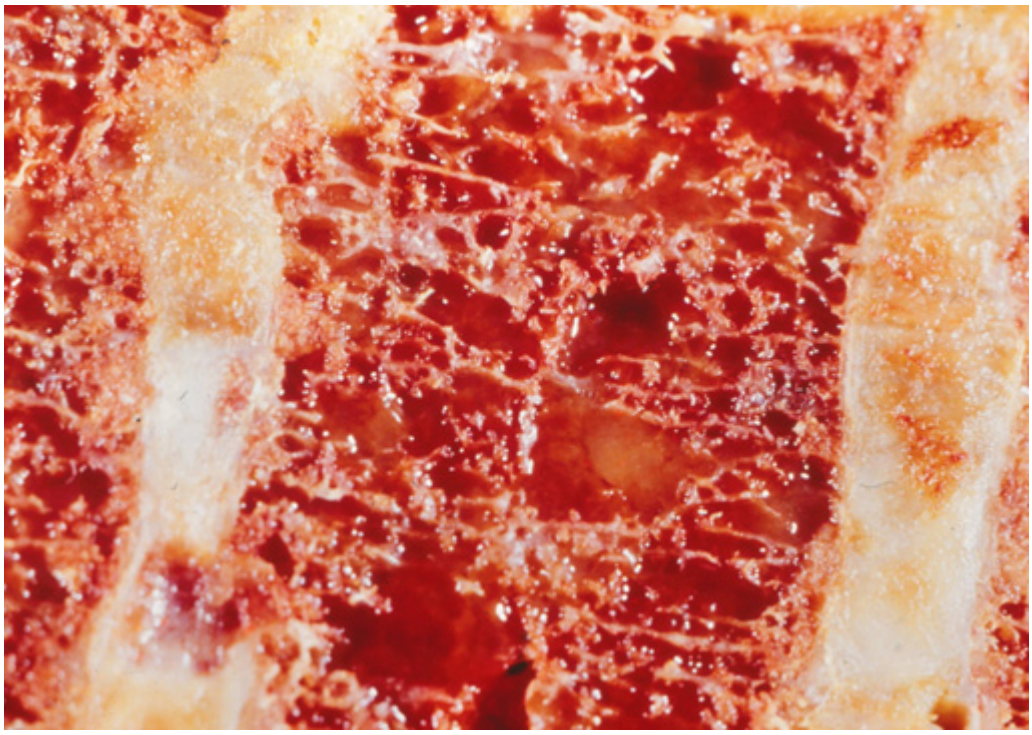

FIGURE 25-16 Myelomatous involvement of vertebral body.Osteolytic lesions in which there is destruction of trabecular bone are present and filled with an infiltrate of neoplastic plasma cells that has a gelatinous gross appearance.

Multiple Myeloma—Clinical Variants

Smoldering MM (SMM; Asymptomatic MM)

About 8% to 14% of patients with MM are asymptomatic at the time of diagnosis.[20,75] These patients have 10% or more bone marrow PCs and/or M protein at myeloma levels but lack related end-organ impairment (**Box 25-3**).[28,76]

The median level of serum M protein in patients with SMM is 2 g/dL, and the median bone marrow clonal PCs burden is approximately 20%.[77] Approximately 70% of patients have

monoclonal LCs in urine, and polyclonal Igs are decreased in more than 80% of patients.[20,29,78] PCs are cytologically atypical in bone marrow aspirate smears, and focal aggregates of PCs, interstitial infiltration, or both are found in biopsy sections.[20]

Although most patients with SMM remain clinically stable for a long time, they are much more likely to progress to symptomatic MM than are individuals with MGUS.[20,79,80] However, the risk of progression is not static.[81] Rather, the likelihood of disease progression is highest during the first 5 years after diagnosis, approximately 10% per year. The rate of progression then drops significantly to 3% annually during the subsequent 5 to 10 years, and finally to 1% per year in patients 10 or more years out from their initial diagnosis of SMM, a rate of disease progression comparable to that of MGUS. These kinetics are a reflection of the significant heterogeneity of SMM, in which three patient groups exist, including those with MGUS-like disease, patients in whom slow progression to symptomatic MM will occur, and finally, patients whose disease is in evolution to symptomatic MM at the time of presentation with SMM and who will manifest overt disease progression in less than 2 years.[20,81] It should be noted that 25% to 30% of patients with SMM never develop symptomatic disease.

In the past, patients with SMM were rarely treated until the onset of myeloma-related symptoms, as earlier therapeutic intervention showed no clinical benefit. With the advent of more effective and less toxic therapeutics, there is now considerable interest in assessing whether early therapy might improve clinical outcomes in patients with SMM who are at high risk for disease progression. Several risk stratification models have been developed that rely on various

parameters, including the bone marrow PC burden, M-protein level, SFLC ratio, predominance within the PC compartment of phenotypically aberrant cells, and presence of immunoparesis.[77,82,83] Such models are imperfect, as there is low concordance among them in the identification of patients with SMM who are at high risk. Moreover, the decision to treat in the context of most clinical trials in which these models are used is made on a single, static assessment based on factors that may lack reproducibility. To date, only one clinical trial has shown improved overall survival in high-risk patients with SMM receiving therapy compared with observation alone.[84] The decision to treat otherwise asymptomatic patients is a complicated one in an overall elderly patient population. Though less toxic than historical therapy, current myeloma therapeutics nevertheless involve toxicities and may have a significant negative effect on quality of life, to say nothing of the financial and psychological burden of preemptive treatment.[81]

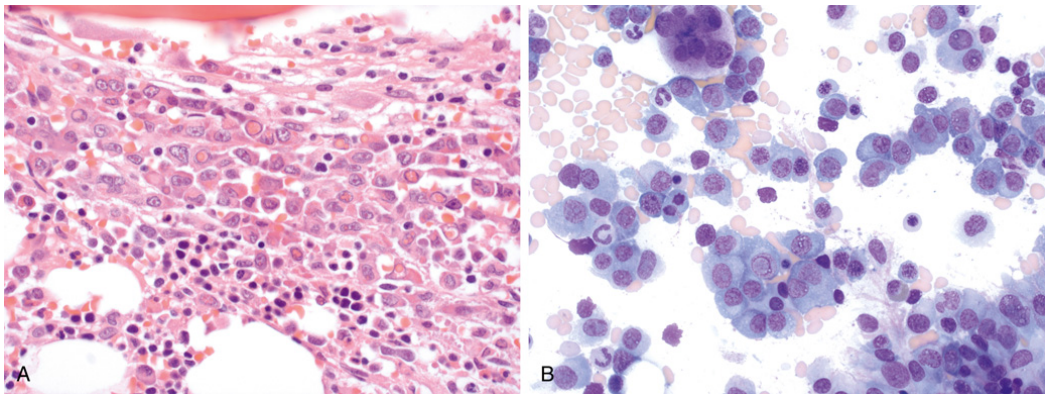

FIGURE 25-17 Myeloma with nuclear pseudoinclusions.**A,** Large nuclear pseudoinclusions (Dutcher bodies) are present in many neoplastic plasma cells. **B,** A myeloma cell containing a prominent Dutcher body (bone marrow biopsy and aspirate; H&E and Wright-Giemsa stains).

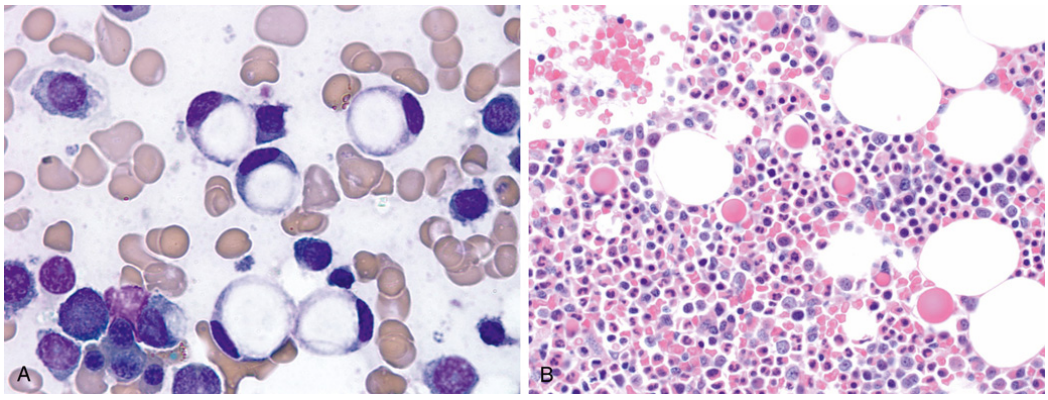

FIGURE 25-18 Myeloma with cytoplasmic vacuoles and inclusions.**A,** The neoplastic plasma cells (PCs) in this case contain single large cytoplasmic vacuoles, imparting a signet ring cell appearance. **B,** In this case, single large Russell bodies are present in several neoplastic PCs, distorting and obscuring the plasmacytic features of the cells (bone marrow aspirate and biopsy; Wright-Giemsa and H&E stains).

Plasma Cell Leukemia (PCL)

PCL is a myeloma variant in which circulating neoplastic PCs are present in the blood. The neoplastic PCs also commonly infiltrate extramedullary sites, including liver and spleen, the central nervous system, and the pleural and peritoneal cavities. Primary PCL is, by definition, present at the time of initial diagnosis, whereas secondary cases develop during the disease course in patients with relapsed or refractory myeloma; primary PCL accounts for approximately 60% to 70% of cases.[85] Primary PCL is a distinctive type of MM with characteristic cytogenetic and molecular findings and an aggressive clinical course with short remissions and survival.[27] Primary PCL is

found in approximately 2% to 4% of myeloma cases.[85-88] Secondary PCL is detected in approximately 1% of previously diagnosed MM cases.[89]

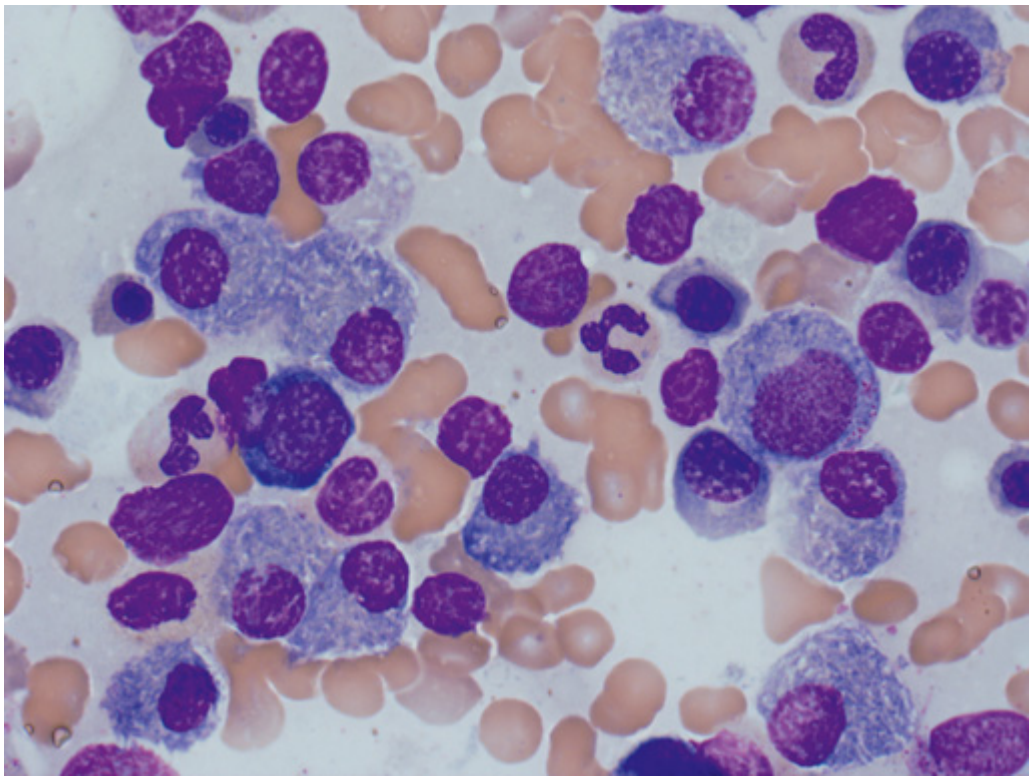

FIGURE 25-19 Myeloma with cytoplasmic inclusions.The neoplastic plasma cells contain abundant irregular cytoplasmic inclusions that impart an appearance reminiscent of Gaucher-type storage histiocytes (bone marrow aspirate; Wright-Giemsa stain).

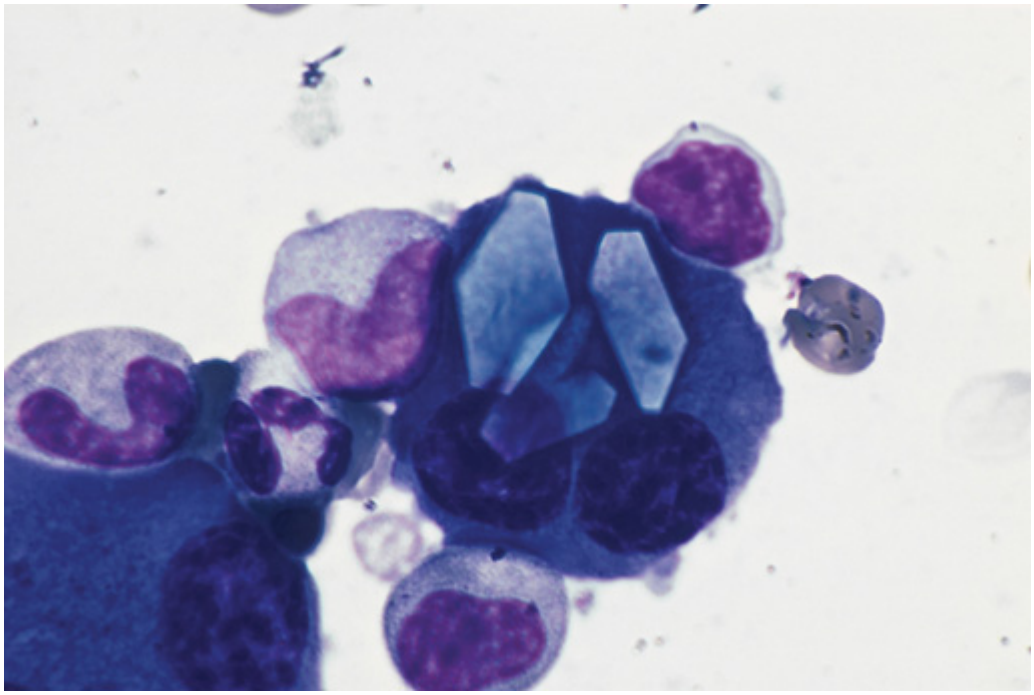

FIGURE 25-20 Myeloma with cytoplasmic crystals.Large binucleate plasma cell containing prominent cytoplasmic crystals (bone marrow aspirate; Wright-Giemsa stain).

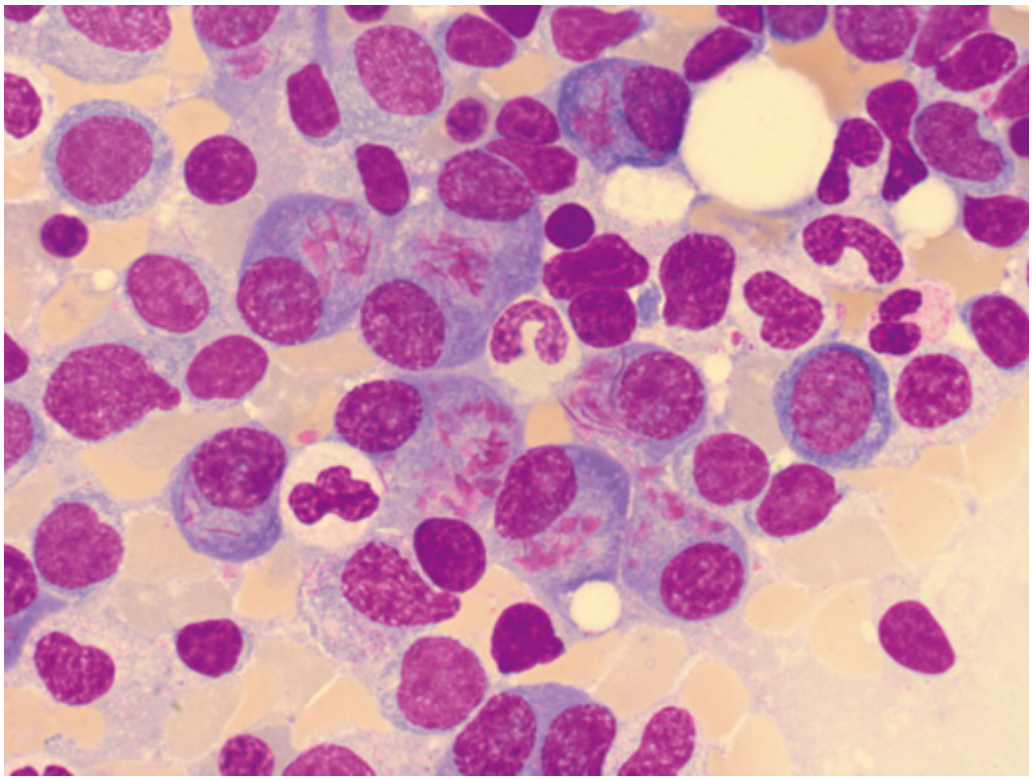

FIGURE 25-21 Multiple myeloma (MM) with cytoplasmic crystals.The neoplastic PCs contain abundant needle-like immunoglobulin inclusions that resemble Auer rods (bone marrow aspirate; Wright-Giemsa stain).

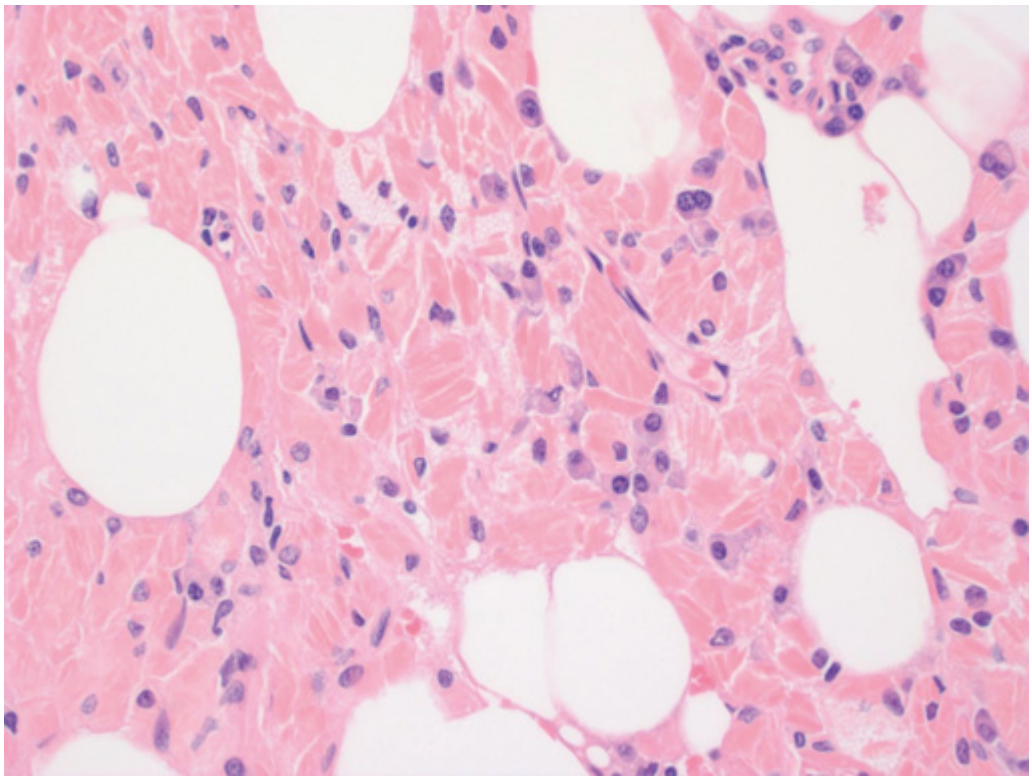

FIGURE 25-22 Myeloma with crystal-storing histiocytosis.In this case, much of the marrow is filled with large histiocytic cells containing refractile crystals that overshadow the admixed myeloma cells that are present singly and in small aggregates. Crystal-storing histiocytes superficially resemble storage-type histiocytes (bone marrow biopsy; H&E stain).

Circulating clonal PCs are detected at low levels in a significant fraction of patients with PCNs, depending on the sensitivity of the analytic methodology used. Historically, the diagnosis of primary PCL was based on the arbitrarily defined criteria of clonal PCs comprising >20% of total leukocytes or an absolute PC count >2 × 10^9/L.[85] However, more recent studies indicate that the clinical

outcome in patients with myeloma with significantly lower levels of circulating PCs is indistinguishable from that of patients with primary PCL.[90,91] In light of this, the IMWG now recommends that patients newly diagnosed with myeloma in whom circulating PCs account for ≥5% of leukocytes based on morphologic enumeration in the blood smear be considered primary PCL.[1,27]

Many of the same clinical and laboratory abnormalities are present in both PCL and typical myeloma. However, PCL is associated with a younger median age at diagnosis. Lymphadenopathy, organomegaly, and renal failure are significantly more common in PCL, and lytic bone lesions and bone pain are less common.[88] Anemia is present in 80% of cases and thrombocytopenia in 50%.[88] Nucleated red cells are often present in blood smears. The leukocyte count is variable but is usually elevated, sometimes markedly so. All types of M proteins have been reported in PCL; however, LC only and IgD myelomas are overrepresented among PCL cases. PCL develops in approximately 20% of IgE MM, a rarely encountered myeloma subtype.[88,92]

The cytologic spectrum of leukemic PCs is similar to that of other myelomas, although anaplastic cells are uncommon in PCL. Though the neoplastic cells typically show overt plasmacytic features, the neoplastic PCs in some cases are larger and may resemble myeloid blasts or peripheralized large cell lymphoma cells (**Fig. 25-24**). The most challenging are PCLs in which the neoplastic cells contain scant cytoplasm and thus resemble small lymphocytes or plasmacytoid lymphocytes. Recognition and accurate enumeration of neoplastic PCs in such cases may be difficult, particularly when the white blood cell count or PC frequency is low, because of their similarity to

normal lymphocytes. Flow cytometry permits unequivocal distinction between PCL and CLL or peripheralized lymphoplasmacytic lymphoma (LPL) (previously discussed). Recognition of circulating PCs with variant morphology is most challenging in the initial diagnostic workup of primary PCL, when blood smear evaluation may occur prior to bone marrow examination or serum protein analysis. The presence of rouleaux provides an important clue to the underlying diagnosis.

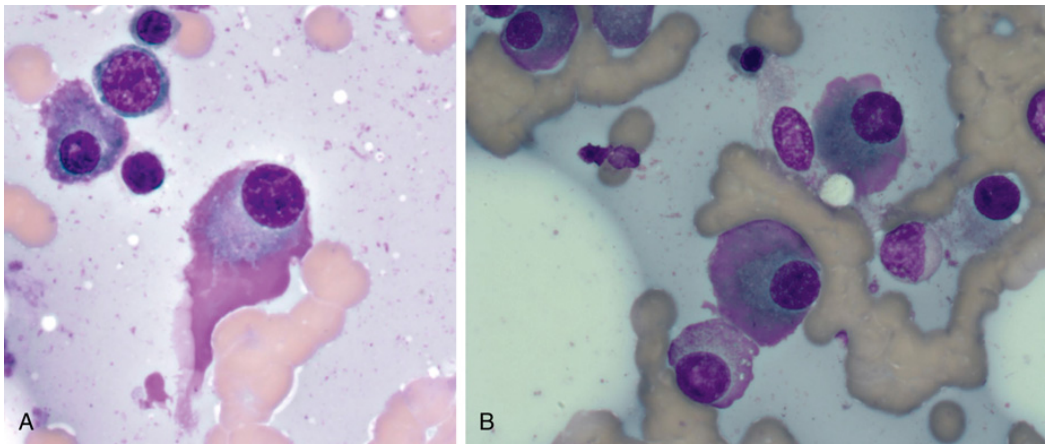

FIGURE 25-23 IgA myeloma.**A** and **B,** In many of the neoplastic plasma cells in this case, the periphery of the cytoplasm is distinctly eosinophilic. Such cells have been termed *flame cells* and are most common in IgA myeloma. This appearance is thought to reflect the higher carbohydrate content of IgA compared with other immunoglobulin (Ig) isotypes (bone marrow aspirate; Wright-Giemsa stain).

An abnormal karyotype is more frequently obtained in PCL than in other myelomas, and there is a higher incidence of high-risk genetics

in both primary and secondary PCL.[86] These include hypodiploidy, del(13q), del(17p) t(14;16), 1q amplification, and 1p losses.[86,93,94] Although usually associated with a favorable prognosis in MM, t(11;14) is overrepresented in primary PCL.[86,94]

Treatment is similar to that for other advanced myelomas. Even with the advent of therapies incorporating bortezomib and immunomodulatory agents, PCL continues to be an aggressive disease, with a poorer response to therapy and significantly shorter survival than those of typical myeloma.[27,95-97] Patients with secondary PCL have a shorter survival than those with primary PCL, 1.3 months versus 11.2 months, respectively.[94] The high frequency of unfavorable genetic abnormalities only partially explains the poor prognosis of PCL.[86,93,98]

Nonsecretory Multiple Myeloma

Nonsecretory multiple myeloma (NS-MM) is defined as MM with no evidence of M protein as assessed by serum or urine IFE analysis and accounts for about 3% of all myelomas.[29,99-102] Myelomas lacking a detectable M protein by IFE are further subdivided by some investigators using additional analytic tools.[103] Oligosecretory MM has a clonal LC detectable by SFLC analysis and accounts for approximately two-thirds of NS-MM cases.[42] SFLC-negative cases in which the clonal PCs express detectable Ig expression as assessed by IHC or intracytoplasmic staining by flow cytometry represent bona fide NS-MM. Finally, rare SFLC-negative, Ig IHC-negative myelomas are designated as nonproducer MM.[32] Acquired mutations of the Ig LC variable genes or alteration of the constant region account for the nonsecretory state in these cases.[104,105] Patients with secretory

myeloma at the time of diagnosis may occasionally become NS or oligosecretory at relapse. NS-MM should be distinguished from rare IgD and IgE myelomas that generally have low-level paraproteinemia and may not be routinely screened for by immunofixation. The cytologic and histologic features and immunophenotype of NS-MM are similar to those of other myelomas. Other than overrepresentation of t(11;14), the spectrum of genetic abnormalities in NS-MM is similar to that of typical myeloma.[101]

The clinical features of NS-MM are generally similar to those of secretory myeloma, except for a lower incidence of renal insufficiency and hypercalcemia and less suppression of normal polyclonal Ig.[29,106] The presence of osteolytic lesions, absence of an M protein, and lower incidence of renal failure in NS-MM often raises clinical suspicion of metastatic carcinoma or other solid tumor. Treatment of NS-MM is the same as that for other MMs. The effect of the NS state on clinical outcome is unclear, as studies have shown variable survival differences between patients with NS and secretory MM.[100-102] Similar to other myelomas, the prognosis of NS-MM has improved significantly in the past decade.

Differential Diagnosis

The most common differential diagnosis among the PC neoplasms is that of early myeloma versus MGUS or a reactive bone marrow plasmacytosis. In most cases, this is not difficult because the composite clinical and pathologic findings required for a diagnosis of myeloma are lacking in MGUS and in reactive PC proliferations. Only when the M protein or percentage of bone marrow PCs are at

the high extreme for MGUS is the distinction from asymptomatic myeloma problematic. In some patients, differentiation of early myeloma and MGUS is not possible at the time of initial evaluation. Close observation and monitoring for evidence of progression to overt malignancy must be continued indefinitely.

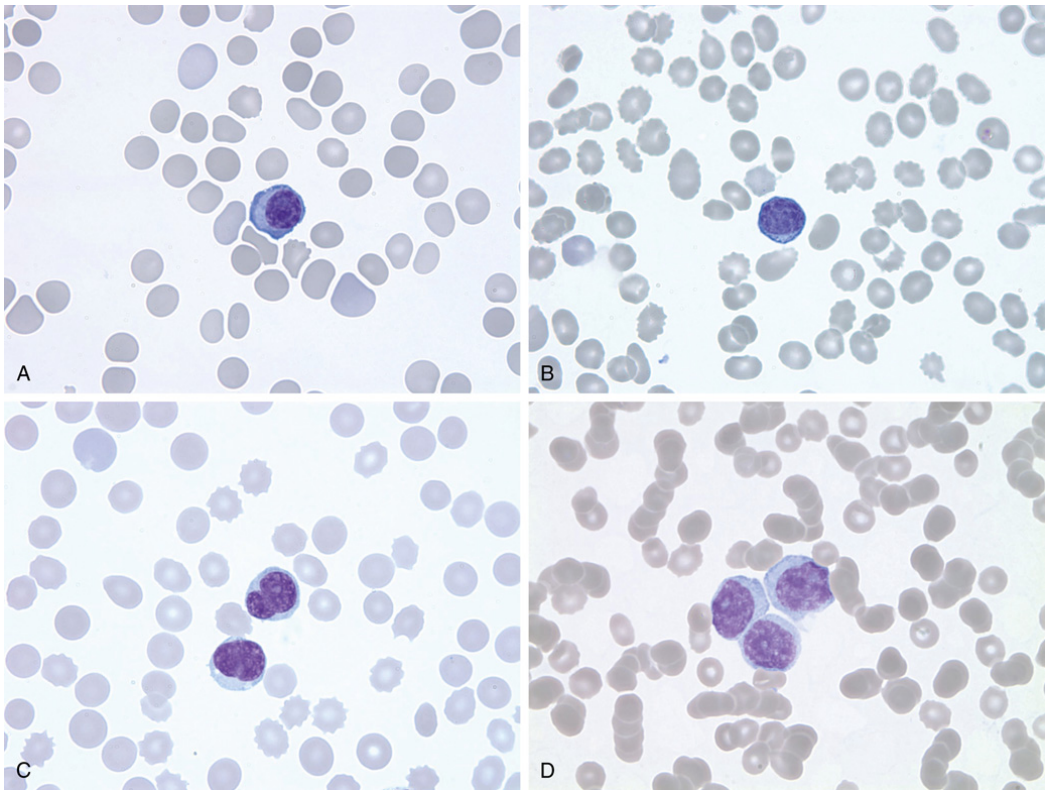

FIGURE 25-24 Cytologic heterogeneity in plasma cell leukemia.**A,** The circulating neoplastic cells usually show overt plasmacytic features. **B,** In some cases, the neoplastic cells resemble small lymphocytes with more subtle evidence of plasmacytic differentiation. Such cases may be mistaken for chronic lymphocytic leukemia or peripheralized lymphoplasmacytic lymphoma. **C,** Leukemic plasma cells (PCs) in this case show nuclear irregularity and lobation. **D,** Leukemic PCs are large, in some cases raising a differential diagnosis that includes acute myeloid leukemia and peripheralized large cell lymphoma (Wright-Giemsa stain).

Reactive bone marrow plasmacytosis of 10% or more may occur in several conditions, including viral infections, immune reactions to drugs, autoimmune disorders such as rheumatoid arthritis and lupus, and HIV/AIDS. Reactive plasmacytosis is distinguished from myeloma by the lack of M protein in the serum or urine in most instances. The PCs are generally mature appearing and show polytypic LC expression by IHC (**Fig. 25-25**).

The rare systemic polyclonal immunoblastic proliferations are among the most difficult reactive plasma cell proliferations to differentiate from myeloma.[107] The disorder usually presents as an acute systemic illness with fever, lymphadenopathy, hepatosplenomegaly, and frequently autoimmune manifestations; anemia and thrombocytopenia are present in most patients. Leukocytosis is typical and includes large numbers of PCs, immunoblasts, and reactive lymphocytes, with eosinophilia and neutrophilia in some cases (**Fig. 25-26**). The bone marrow is heavily infiltrated by immunoblasts, PCs, and reactive lymphocytes (**Fig. 25-26**). Lymph nodes and other organs may also be involved. Marked polyclonal hypergammaglobulinemia is usually present, but an M protein and bone lesions are absent. These polyclonal immunoblastic proliferations usually undergo complete resolution after steroid therapy alone.

Occasionally, myeloma must be distinguished from a lymphoma with extreme PC differentiation such as LPL, marginal zone lymphoma, immunoblastic large-cell lymphoma, plasmablastic lymphoma, or ALK-positive large B-cell lymphoma (**Fig. 25-27**). Any of these may show morphologic similarities to myeloma and be associated with M protein. In most cases, lymphomas with PC

differentiation present with extramedullary disease, and at least some of the diagnostic criteria for myeloma are lacking. Thorough morphologic, immunophenotypic, and genetic characterization will usually distinguish these tumors from myeloma. The identification of a clonally related B-cell population aids in the distinction of myeloma from low-grade B-cell lymphomas, including LPL and marginal zone lymphoma.[108,109]

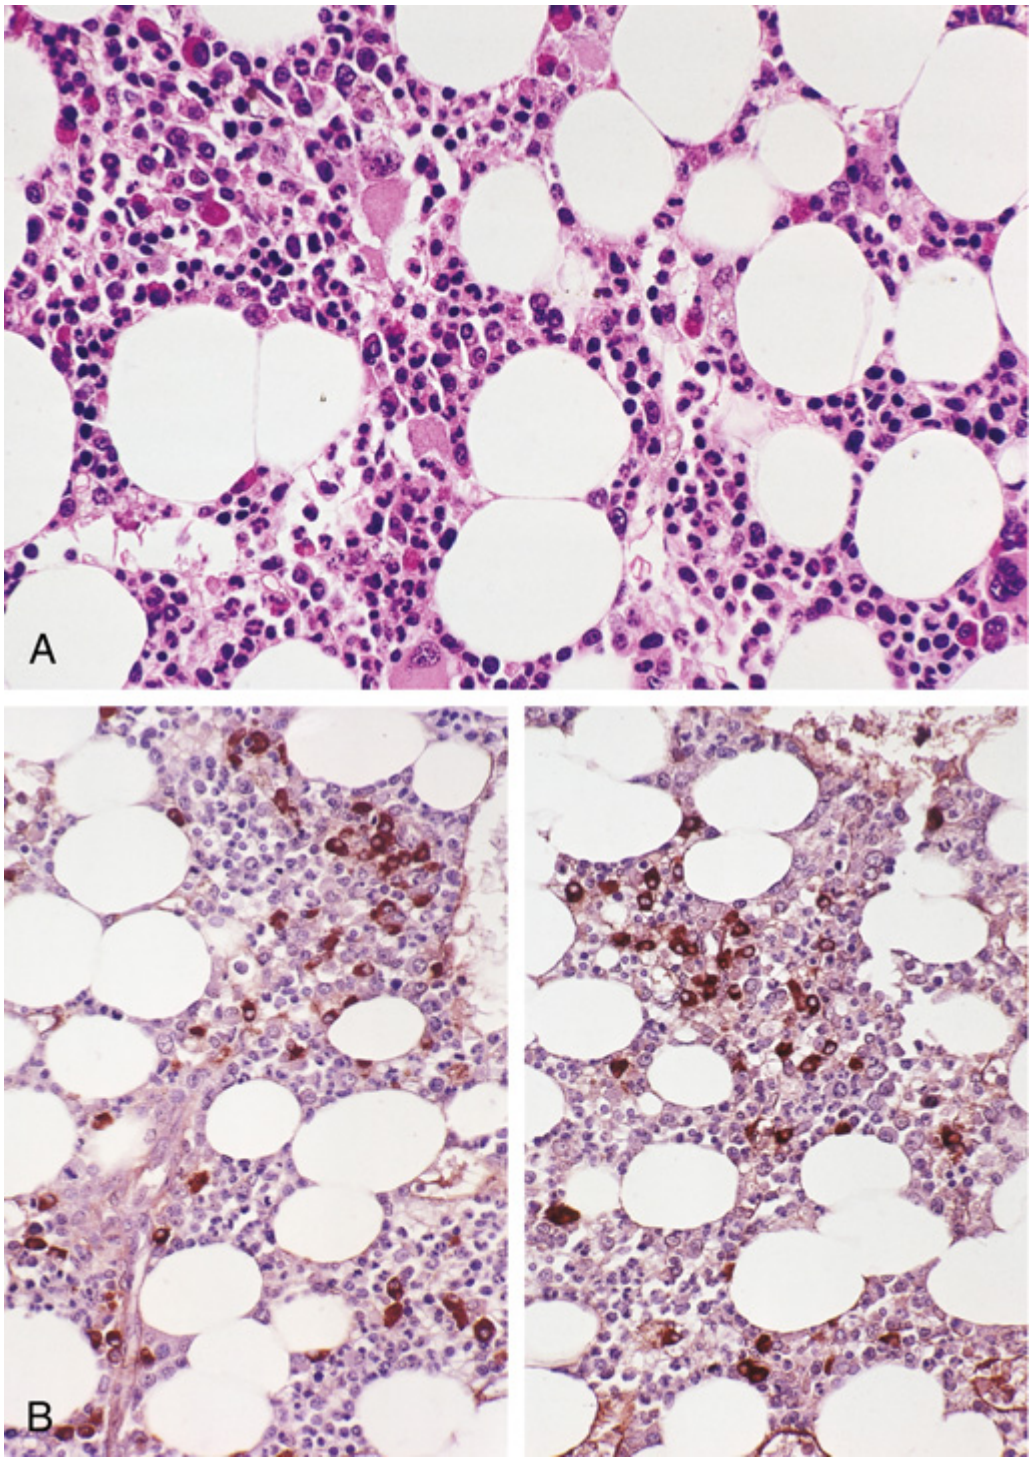

FIGURE 25-25 Reactive bone marrow plasmacytosis.**A,** In this case, plasma cells are increased but mostly scattered in an interstitial pattern with a few small clusters (H&E stain).

Immunohistochemistry (IHC) for kappa **(B)** and lambda **(C)** light chains showed a polyclonal staining pattern, consistent with a reactive plasmacytosis (kappa and lambda IHC).

Myelomas composed of small lymphoid-appearing PCs often express CD20 and may mimic an LPL or marginal zone lymphoma with extreme PC differentiation. They are readily distinguished from lymphoma by cyclin D1 positivity and identification of t(11:14) by FISH.[61,63] Plasmablastic lymphoma usually differs from plasmablastic myeloma in clinical presentation, including its frequent association with HIV and Epstein-Barr virus (EBV). In clinically atypical cases, especially when the bone marrow is involved at presentation, there may be no defining features that distinguish the two disorders.[110,111]

PCL in which the neoplastic PCs are small with lymphoid features may be especially difficult to differentiate from CLL or a peripheralized LPL. The combination of clinical findings, type of M protein, bone marrow examination, immunophenotype, and genetics usually leads to the appropriate diagnosis.

Several metastatic tumors may present with lytic bone lesions and bear morphologic resemblance to myeloma. Thorough IHC evaluation is key to distinguishing metastatic neoplasms from myeloma.

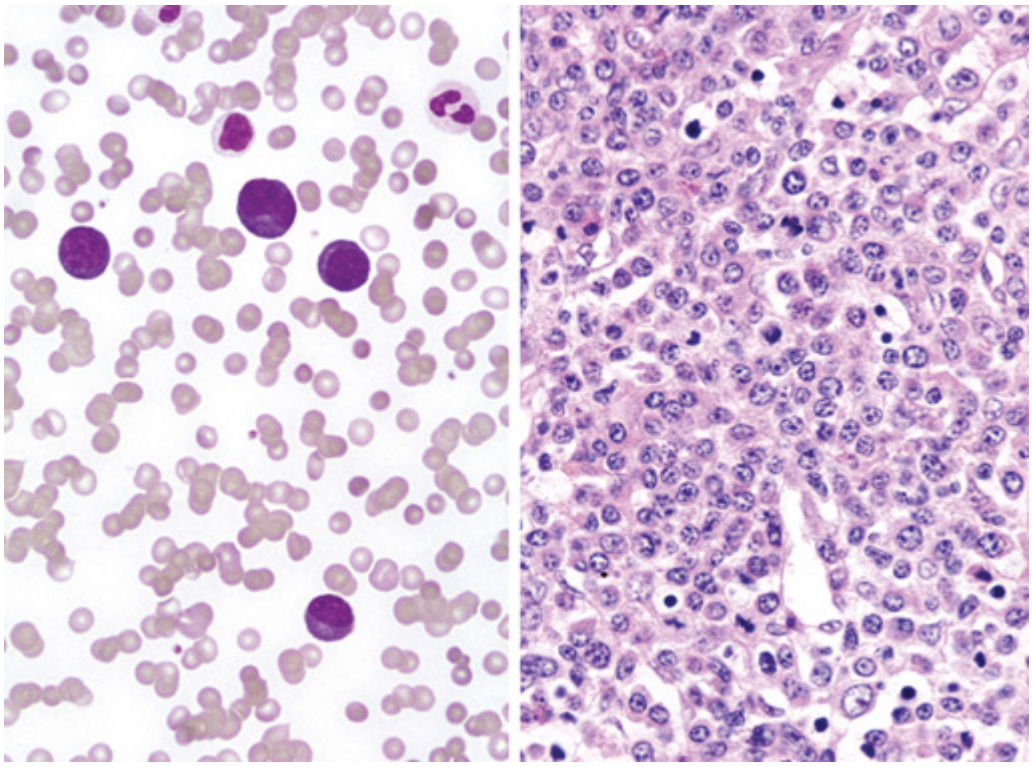

FIGURE 25-26 Systemic polyclonal immunoblastic reaction.Blood smear and bone marrow section from a middle-aged female patient with recent-onset renal failure and hypergammaglobulinemia. The blood smear contains numerous plasma cells (PCs), immunoblasts, and reactive lymphocytes **(A)**. The marrow is hypercellular, with clusters of immature PCs and immunoblasts **(B)**. The hypergammaglobulinemia is polyclonal. Light chain immunohistochemistry (IHC) performed on the bone marrow biopsy confirms a polyclonal PC and immunoblast proliferation. The patient is diagnosed with lupus. The polyclonal immunoblastic reaction promptly resolved with

corticosteroid therapy (Wright-Giemsa and H&E stains).

Immunophenotypic Features of Normal and Neoplastic Plasma Cells

Normal Plasma Cells

PCs are generally defined immunophenotypically by bright CD38 expression. CD38 expression is not specific to PCs, as it is seen at various levels on virtually all other nucleated marrow subsets, but normal PCs express higher levels of CD38 than any other normal hematolymphoid cell population.[112-115] PCs also express CD138, and this antigen is essentially specific to PCs among hematolymphoid cells.[116-118] Normal bone marrow PCs usually express CD19 and CD45 and are negative for CD20 and CD56.[113,117,119-123] However, minor subsets of normal bone marrow PCs deviate from each of these prototypic features.[124-127] Notably, some antigens are modulated on the basis of the maturational stage; as they mature, PCs show decreasing intensity of CD45 and CD19 and increasing CD138.[117,128,129] A normal CD19-negative, CD56-positive PC population has been detected in bone marrow, and it is postulated to represent a terminally differentiated, long-lived subset.[127] A typical example of normal bone marrow PCs is shown in **Figure 25-28**. Additional immunophenotypic findings in normal PCs include bright expression of CD27 and CD81 and lack of CD28, CD117, and CD200.[117,125,126,130,131] These markers are useful to compare normal and abnormal PCs (**Table 25-4**). Normal PCs express polytypic cytoplasmic Ig, with kappa-to-lambda ratios in the range of 1 to 2:1, but occasionally as high as 4:1. It is important to recall that

an elevated kappa-to-lambda or lambda-to-kappa ratio does not always indicate clonality; aberrant surface antigen expression should be evaluated in conjunction with cytoplasmic LCs.

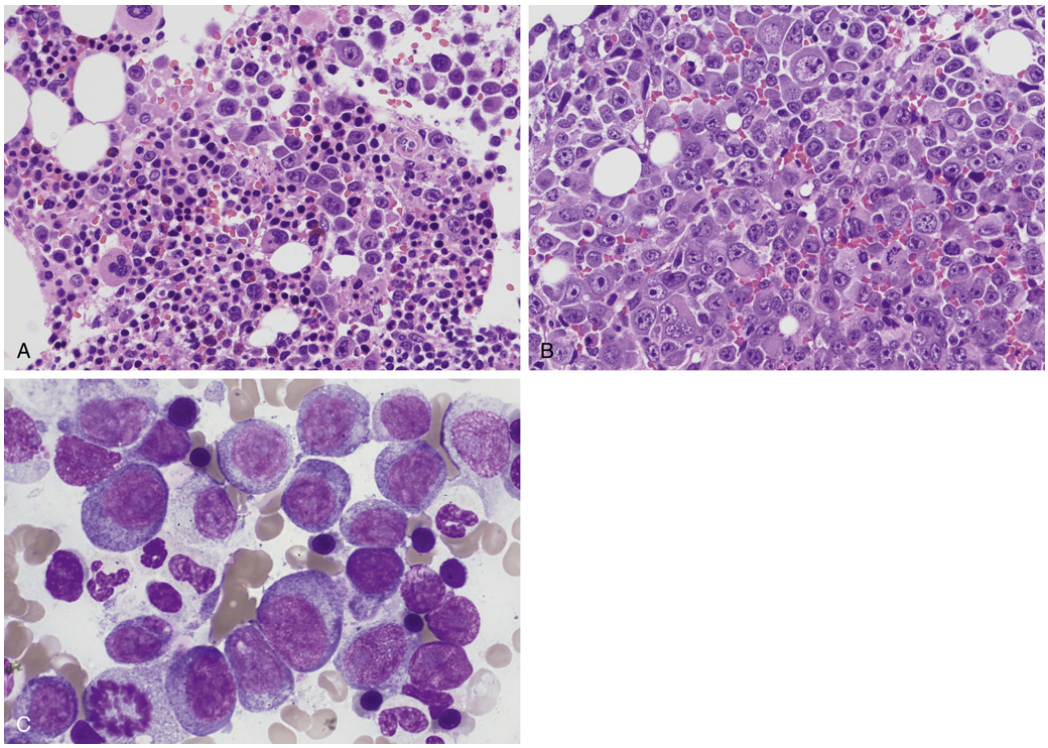

FIGURE 25-27 ALK-positive large B-cell lymphoma involving the bone marrow.**A** and **B,** In some areas, small clusters of neoplastic cells are present, whereas diffuse lymphomatous infiltrates are present elsewhere. The neoplastic cells have plasmablastic features and are morphologically indistinguishable from high-grade myeloma **(C)** (H&E and Wright-Giemsa stains). The tumor cells were positive for CD138, lambda light chain, and ALK (not shown).

Neoplastic Plasma Cells

Myeloma cells deviate immunophenotypically from their benign counterparts in virtually all cases (**Table 25-4**). Like their normal counterparts, myeloma cells express CD38 and CD138, but CD38 can be dimmer than that in normal PCs.[117,124] CD138 is used in most flow cytometry assays, but its expression can be biologically variable.[132] Moreover, the CD138 antigen is sensitive to the typical preanalytic specimen processing used in flow cytometry, including permeabilization and washes, which may compromise its subsequent detection. Thus, CD38 is often a more robust marker than CD138, except in those instances where it is used as a drug target (discussed later in this chapter). CD38 intensity in MM usually exceeds that of other marrow populations, but occasionally there is significant overlap with other cell types. CD19 is absent in about 95% of myelomas, whereas CD56 is expressed in 60% to 80%. The reported percentage of myelomas that express CD45 varies widely, ranging from 18% to 75%. These differences likely result from both technical issues and biological issues. Regarding the latter, as previously described, CD45 decreases with maturation of PCs, and variability of CD45 expression is a common feature in myeloma; the PCs with the brightest CD45 represent the proliferative compartment.[122,128,133] Therefore, it would not be surprising to find variation in CD45 expression depending on disease stage or as a consequence of therapy. Reported variability of CD45 in MM cases during the course of disease supports this notion.[134]

Abnormal PCs can be found both in monoclonal gammopathy of undetermined significance (**Fig. 25-29**) and newly diagnosed MM (**Fig. 25-30**). The percentage of PCs by flow cytometry should not be

used for disease categorization (morphology is the gold standard), but one should note the proportion of clonal and nonclonal PCs within the marrow. In many cases of MGUS, there is a mix of clonal and polyclonal PCs. The percentage of clonal PCs may predict disease progression in MGUS and SMM.[83]

Technical Issues

General Technical Issues

Several technical issues can be encountered in the flow cytometric evaluation of myeloma that may complicate analysis. First, myeloma cells do not show predictable forward scatter/side scatter and CD45/side scatter patterns and often do not cluster tightly; instead, they require gating that is based on antigen fluorescence parameters, such as CD38 and/or CD138. Next, depending on the details of the processing protocol, myeloma cells tend to adhere to other cell types, particularly granulocytes, creating potentially confusing light scatter and antigen expression, e.g., CD45 and CD10. This phenomenon may be partly responsible for the widely varying reports of the prevalence of CD45 expression in MM. PC-granulocyte doublets should be excluded based on CD45/SS patterns. PCs often show high levels of autofluorescence, greater than other cell populations in the bone marrow.[124] Thus, studies that use internal cell populations (e.g., lymphocytes) as negative controls can overestimate the level of antigen expression. Because of this, some labs have recommended the use of an isotype control tube containing CD38 for the accurate determination of a threshold for positivity specifically for the PC population. Finally, it is well established that myeloma cells are generally underrepresented in flow cytometric analysis when

compared with morphologic aspirate smear evaluation, on average by 60% to 70%.[135-138] The decrement is frequently attributed to hemodilution in a “second pull” bone marrow aspirate.[139] However, PCs often appear to be disproportionately depleted compared with other cell types expected to be affected similarly by hemodilution (e.g., blasts). One explanation is that PCs may be differentially distributed in the liquid versus particle portions of the bone marrow aspirate, and thus may be disproportionately depleted relative to other cellular elements in less particle-rich aspirate specimens.[135] It is also possible that other physical or biological factors of MM affect flow cytometry recovery.[138]

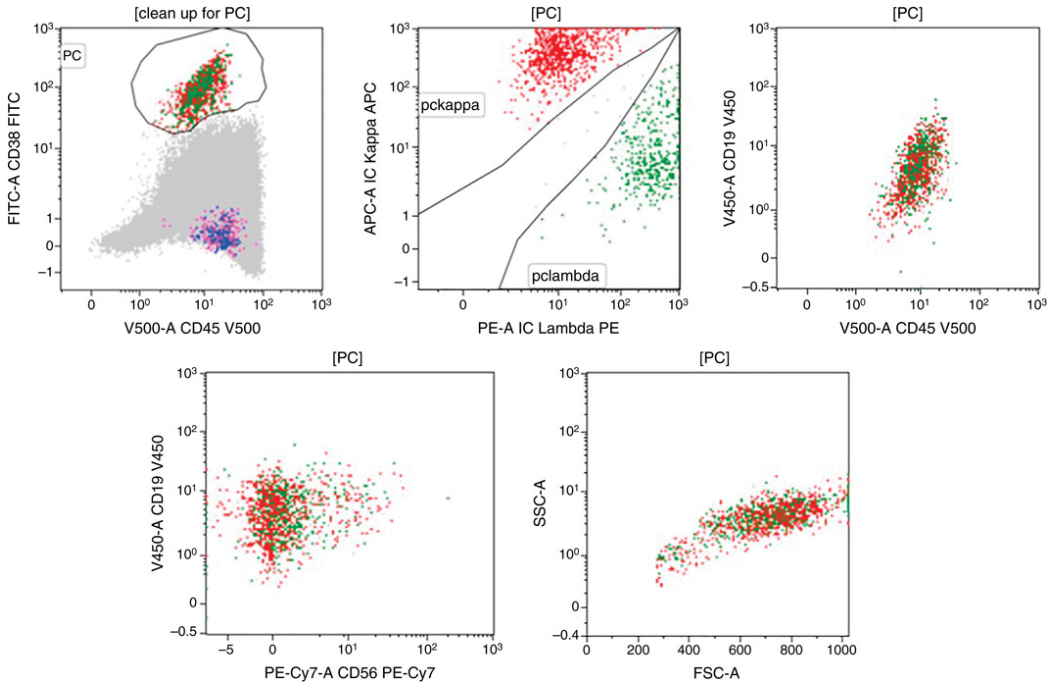

FIGURE 25-28 Phenotype of normal bone marrow plasma cells.Plasma cells (PCs) are selected based on their bright CD38 and slightly dim CD45 expression. They are composed of a mix of PCs that express either cytoplasmic kappa or cytoplasmic lambda LCs, with a normal ratio of ~ 2:1. The PCs express CD19 and CD45, but they lack CD56. They have variably increased size based on forward scatter (FSC) criteria. The cell populations are indicated as follows: magenta, kappa-expressing B cells; blue, lambda-expressing B cells; red, normal kappa-expressing PCs; green, normal lambda-expressing PCs; black, abnormal PC population; and gray, remainder of non-B, non-PC viable singlet mononuclear cells.

Table 25-4

Expression of Cluster of Differentiation Markers on Normal and Abnormal (Neoplastic) Plasma Cells

CD Marker	Normal PC	Abnormal PC
CD19	Positive	Dim to absent
CD20	Negative	Positive (~1/3 of cases)
CD27	Positive	Dim to absent
CD28	Negative	Positive (~1/2 of cases)
CD33	Negative	Positive in a minority of cases
CD38	Bright	Usually bright, but can be dim in some cases even without targeted therapy
CD45	Slightly dim	Variable, can be increased or decreased
CD56	Negative	Positive on a majority of cases (~2/3)
CD81	Positive	Dim to absent
CD117	Negative	Positive in some cases
CD200	Negative	Positive (~3/4 of patients)

CD, Cluster of differentiation; *PC,* plasma cell.

Adapted from Paiva B, Almeida J, Pérez-Andrés M, et al. Utility of flow cytometry immunophenotyping in multiple myeloma and other

clonal plasma cell-related disorders. *Cytometry B Clin Cytom*. 2010;78:239-252.

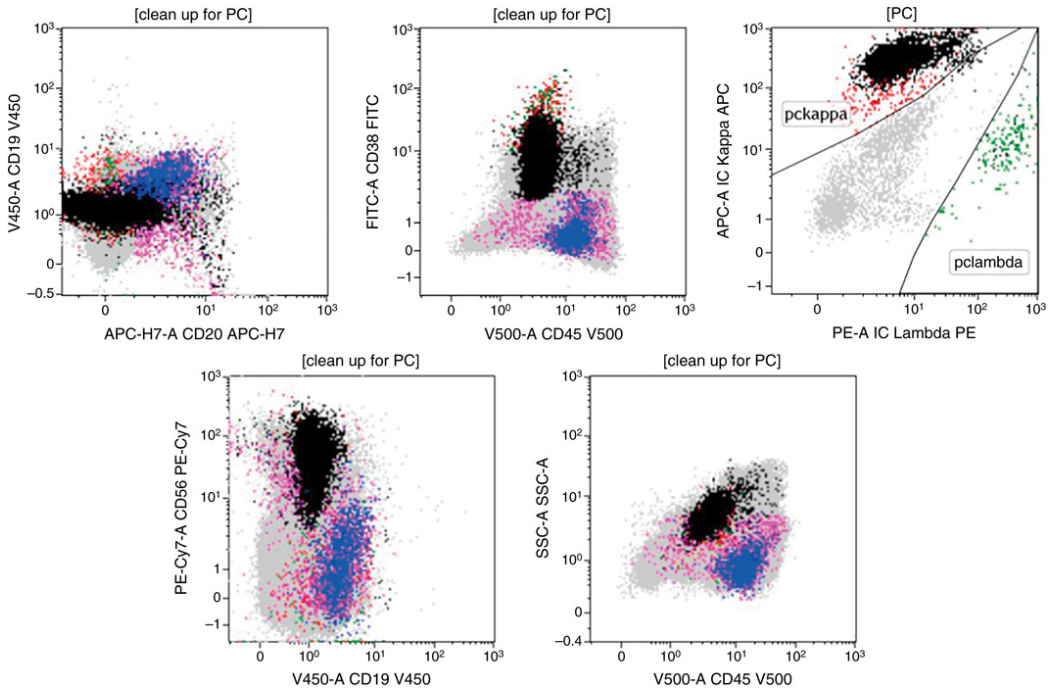

FIGURE 25-29 Monoclonal gammopathy of undetermined significance (MGUS).This example of a non-IgM MGUS demonstrates typical features in that the bone marrow contains both polyclonal and clonal plasma cells (PCs). The abnormal PC population expresses CD19 (dim to absent), CD20 (partial dim), CD38 (slightly dimmer than the normal PCs), CD45, monotypic cytoplasmic kappa immunoglobulin light chains, and bright CD56. Based on CD45 versus side scatter (SSC) plots, the PCs have increased SSC compared with lymphocytes, with slightly dimmer CD45 (overlapping with the traditional “blast gate”). Cell populations are identified as indicated in Figure 25-28.

Technical Issues Related to Minimal Residual Disease Analysis

Minimal residual disease (MRD) analysis is becoming increasingly important when following patients with MM, and flow cytometry has emerged as the method of choice for MRD detection.[140,141] Because of the wide variability in CD45 expression and light scatter characteristics in myeloma, gating requires the use of specific antigens. Gating on bright CD38-positive events is the most widely used approach to myeloma, and this generally suffices at diagnosis. However, in the setting of MRD analysis, bright CD38 gating alone is insufficiently sensitive or specific because of the dimmer CD38 expression in MM and the potential co-occurrence of non-PC events, aggregates, and debris in the bright CD38 region. In addition, CD38-targeted therapy will alter the approach (see subsequent section). Consequently, MRD analysis in myeloma requires gating on more than one marker. Because of its 100% specificity and sensitivity for PCs, CD138 has emerged as a favored marker by some for MRD gating. However, optimization of CD138 assessment may be hampered by technical issues, including clone choice, lyse reagent, and refrigeration.[116] CD38 and CD138 in tandem can be an effective gating strategy, capturing the vast majority of cases.[121,139] If feasible, a three-parameter gate with CD38, CD138, and CD45 appears to be maximally sensitive.[121,139]

The detection of MRD in MM depends on the identification of immunophenotypic aberrancy on the PCs. Simply incorporating CD19 and CD56 has been suggested to capture more than 90% of myeloma MRD.[139] An example of a laboratory-developed MRD assay is shown in **Figure 25-31**. However, the detection of normal CD19-

negative, CD56-positive PC populations raises some concerns about the use of these as the sole criteria for MRD.[125,127,142] It appears that assessment of combinations of multiple antigens with aberrant expression patterns (discussed previously) is required for optimal MRD assessment.[139] The EuroFlow group in 2012 recommended CD19 and CD56 as first-tier makers, followed by assessment of CD27, CD28, CD81, and CD117 as follow-up markers if necessary.[143] Assessment of CD200 also appears promising, but it bears further investigation.[131,144] Because of the need for multiparameter gating and the need to assess multiple aberrantly expressed antigens, high-color flow cytometry (≥6 colors) seems to be optimal for MRD analysis of MM.[122,127,130,145,146] It is worth noting that minor immunophenotypic modulations can occur over time in patients treated for MM, but these are unlikely to compromise a robust analysis that is based on assessment of multiple antigens.[134]

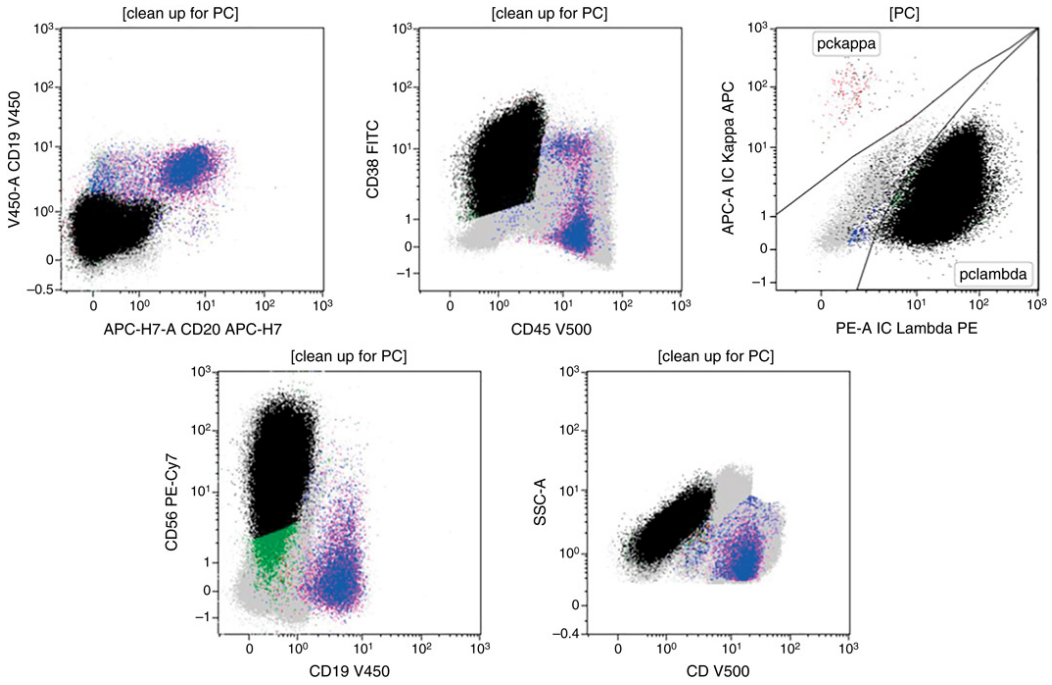

FIGURE 25-30 Typical phenotypic findings in myeloma.In this case, normal plasma cells (PCs) are rare to absent. The abnormal PCs lack CD19 and CD20. CD38 is brighter than the background B cells but dimmer than what is seen in typical polyclonal PCs. The myeloma cells express monotypic cytoplasmic lambda immunoglobulin light chain. CD45 is dim to absent. Cell populations are identified as indicated in Figure 25-28.

In general, a sensitivity of 10^{-4} is considered to be the minimal requirement for a standard sensitivity MRD detection method. The European Myeloma Network Report[139] recommended a minimum of 100 aberrant PC events to make a diagnosis of MRD. Thus, to achieve a sensitivity of 10^{-4}, a total of 1 million events needs to be acquired in a single-tube analysis. Note that this group does not

require all 100 events to be present in the same tube, just that the aberrant PC events across tubes totals at least 100. If one is using a multitube analysis, fewer events need to be acquired per tube to satisfy the European Myeloma Network recommendation.

As molecular diagnostic testing for MRD in myeloma has become more available, there has been simultaneous development of more sensitive flow cytometry assays.[147] Sometimes termed *next generation flow cytometry*, the new assays target a sensitivity down to 10^{-5}. One of the most common methods to do this testing is EuroFlow.[148] The EuroFlow assay uses two 8-color tubes—after bulk-lysing marrow samples, 5 to 10 million cells are stained so that enough events can be collected to achieve the 10^{-5} sensitivity. As this takes a lot of instrument time, 10-color single tube methods have been developed and show similar performance but require much less acquisition time.[148] Regardless of which method a lab chooses for its MRD assay, a careful validation with dilutional studies is critical to make sure the MRD assay works as expected.[149] If a lab is accredited by the College of American Pathologists' Laboratory Accreditation Program, the lower limit of detection must appear in the diagnostic report[150,151]; this will provide greater transparency to ordering providers so that they may discern standard from high (next-generation) flow cytometry myeloma MRD assays.

Technical Issues Related to Therapy Targeting CD38

Daratumumab is a highly effective monoclonal antibody that is widely used to treat patients with myeloma at diagnosis, at relapse, and during maintenance therapy. As CD38 has high antigen density on the surface of PCs, it is useful for a therapeutic target in addition

to being useful for flow cytometric analysis. Daratumumab remains bound to CD38 on PCs for 4 to 6 months, masking the epitopes recognized by most CD38 antibodies used for the identification of PCs by flow cytometry.[152] As a result, novel approaches for the detection of PCs by flow cytometry must be used in the post-daratumumab setting. Multiple cell surface and cytoplasmic PC markers have been evaluated. The EuroFlow tubes use a "multiepitope" or "polyspecific" antibody that seems to detect CD38 to some degree, even in the context of bound daratumumab.[153] Cytoplasmic staining of PCs for CD38 using a monoclonal antibody has been reported and may afford better PC detection than surface staining with the multiepitope CD38 antibody.[153] Multiple other cell surface markers have been tested, including CD54, CD229, and CD319; one study suggests that CD319 (SLAMF7) is superior for the identification of PCs (**Table 25-5**).[154] In addition, p63 (VS38 or VS38c) is a rough endoplasmic reticulum protein and is strongly expressed in PCs. Although one lab reported difficulty in using cytoplasmic p63/VS38 in its assay,[155] three other studies have demonstrated that analysis of p63/VS38 expression is highly sensitive for the detection of PCs after daratumumab therapy (**Fig. 25-32**).[156-158]

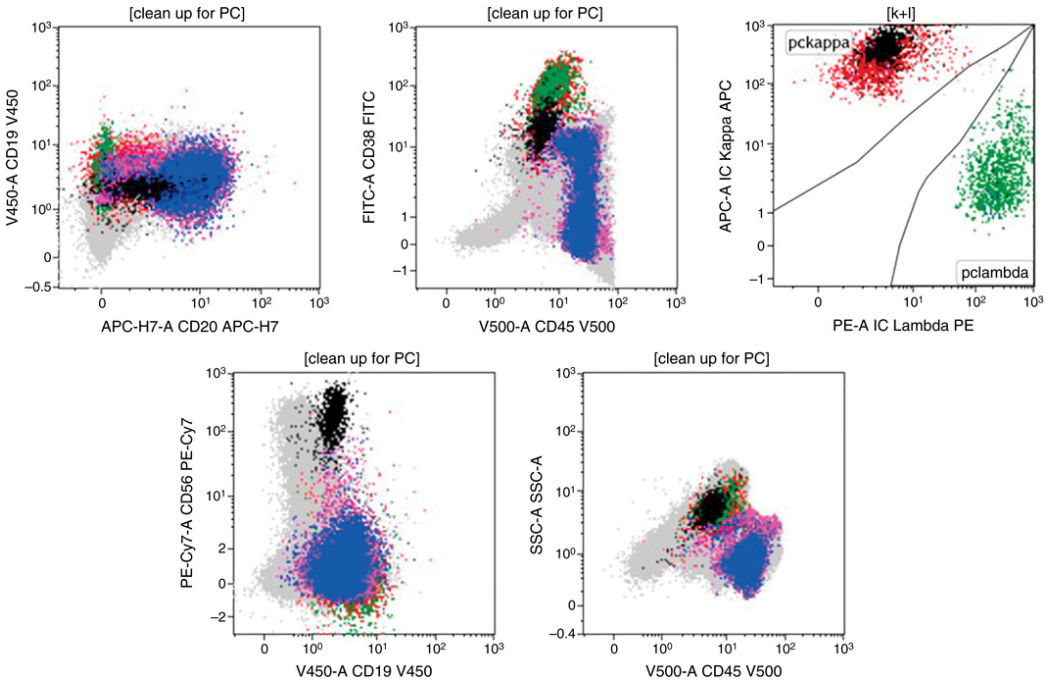

FIGURE 25-31 Minimal residual disease (MRD) detection in myeloma.This laboratory-developed MRD assay demonstrates how multiple antigens can have a population of abnormal plasma cells (PCs) that has an immunophenotype that is different from normal plasma cells in the background. The abnormal PC population is kappa monotypic and expresses CD38 (dim), CD45 (slightly dim), and CD56 but lacks CD19 and CD20. Though this population is relatively easy to detect by flow cytometry, bone marrow biopsy sections and immunohistochemistry are negative for clusters of clonal PCs. Cell populations are identified as indicated in Figure 25-28.

Table 25-5

Alternative Plasma Cell Flow Cytometry Antigens for Patients Exposed to Anti-CD38 Therapy (Daratumumab)

Marker	Surface or Cytoplasmic
CD38-multiepitope	Surface
CD38-monoclonal	Cytoplasmic
p63 (VS38c or VS38)	Cytoplasmic
CD319 (SLAMF7)	Surface
CD54	Surface
CD229	Surface

Diagnostic Utility of Flow Cytometry

Flow cytometry contributes to the diagnosis of MM by identification of clonal and phenotypically aberrant PCs. Although the diagnosis of MM is generally not dependent on the findings of flow cytometry, it may play a decisive role in the differential diagnosis in some cases, as discussed later in this chapter. The following examples show how flow cytometry can be used in conjunction with data collected from bone marrow morphology, IHC, and protein electrophoresis/immunofixation, etc. to arrive at the correct diagnosis.

Unusual Morphologic and Immunophenotypic Variants of Myeloma

CD20-Positive Plasma Cell Myeloma

Occasionally, myelomas are encountered that are difficult to recognize by morphologic evaluation, especially anaplastic myelomas and those with striking lymphoid or lymphoplasmacytoid cytologic features. Detection of a characteristic immunophenotype by flow cytometry will help discriminate these from other neoplasms. It is worth mentioning that expression of CD20 in MM is often associated with lymphoplasmacytoid morphology, creating an additional diagnostic challenge (**Fig. 25-33**).[63] Notably, however, co-expression of CD19 and CD20 in MM is extremely rare; thus, when one sees a B-lineage neoplasm expressing CD20 but lacking CD19, it is more likely to represent a PC neoplasm than B-cell non-Hodgkin lymphoma.

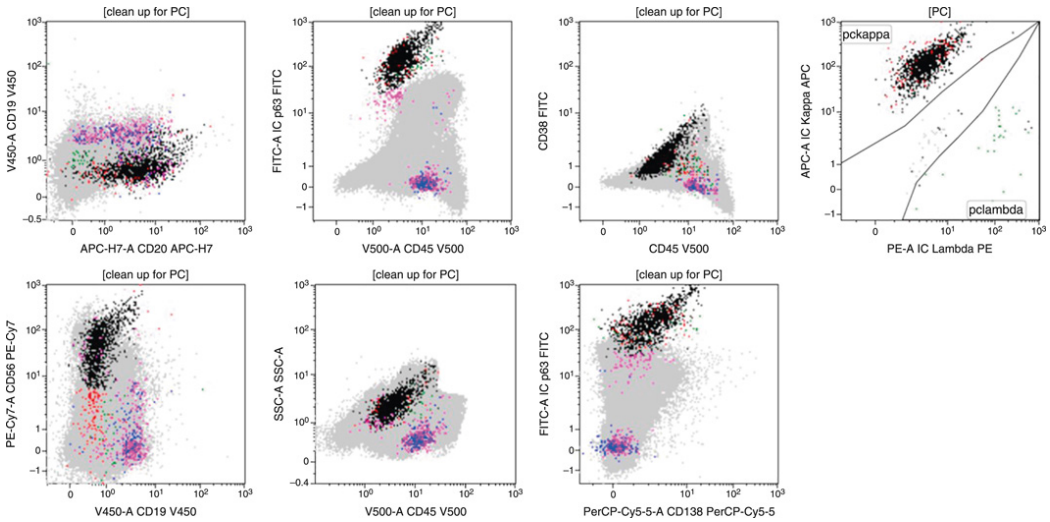

FIGURE 25-32 Detection of myeloma cells after treatment with daratumumab.Daratumumab binds to CD38 and interferes with flow cytometric detection for 4 to 6 months. As seen in the CD38 versus CD45 dot plot, all mononuclear cells, including plasma cells (PCs), have dim-to-absent CD38 expression. As CD138 can have variable expression (does not discriminate the population well in this example), this laboratory developed test stains for cytoplasmic p63 (VS38). All PCs in the sample (clonal and polyclonal) clearly separate based on CD45 versus intracytoplasmic p63. The abnormal PC population is kappa monotypic and expresses CD20 and CD56 but lacks CD19 and CD45. Cell populations are identified as indicated in Figure 25-28.

Unusual Expression of Cytoplasmic Light Chains in Myeloma

There are a variety of reagent antibodies that can be used to detect cytoplasmic LCs in PCs by flow cytometry and IHC. Reagent antibodies can be either polyclonal or monoclonal, and they are conjugated to a variety of different fluorochromes. Clonal LC proteins in neoplastic myeloma cells may be abnormal because of truncation or antigenic variation resulting from somatic hypermutation. Such variant LCs may not be well recognized by the reagent antibodies routinely used for LC analysis (**Fig. 25-34**).

In rare instances, PC neoplasms may express both kappa and lambda LCs (**Fig. 25-35**). Rarely, no demonstrable expression of either kappa or lambda LCs is detected; such myelomas are termed *nonproducers* (**Fig. 25-36**). Such cases are distinguished from nonsecretory MM in which LC restriction is readily demonstrated by either flow cytometry or IHC despite the absence of a detectable urine or serum M protein by IFE and a normal SFLC ratio.

Plasma Cell Leukemia

The clinical features of newly diagnosed MM may be unusual in some patients and may, as a result, mimic other hematolymphoid neoplasms. Primary PCL is a notorious example. As discussed previously, hematopathologists may encounter cases of PCL prior to bone marrow examination and with no knowledge of laboratory or radiologic findings. Moreover, PCL may morphologically resemble other hematolymphoid malignancies, including CLL, AML, or even peripheralized large cell lymphoma, depending on the cytologic features of the circulating PCs. Flow cytometry is often essential for

demonstrating the plasmacytic differentiation of the neoplastic cells and confirming the diagnosis of PCL (**Fig. 25-37**). The immunophenotypic features of PCL are generally similar to those of conventional MM, except for more frequent expression of CD20 in PCL and the less frequent expression of CD56, which is lacking in approximately 80% of cases (**Fig. 25-24**), CD117, and HLA-DR.[85,88,159,160]

Monoclonal Gammopathy Of Undetermined Significance

Definition

MGUS is the designation for a monoclonal Ig in the serum or urine of a patient in whom there is no evidence of MM, amyloidosis, Waldenström macroglobulinemia or other lymphoproliferative disorders, or any other disease known to produce monoclonal Igs. In most instances, the patient will not develop a malignant PC neoplasm during their lifetime, but there is eventual progression to one in a significant minority of cases.

There are two distinctive categories of MGUS: IgM MGUS and non-IgM MGUS (**Box 25-6**). Non-IgM MGUS accounts for approximately 85% of cases, is caused by an underlying clonal PC population, and may progress to a malignant PC neoplasm, including MM or amyloidosis. In contrast to previous WHO classifications, the ICC recognizes two subtypes of IgM MGUS: IgM MGUS PC type and IgM MGUS, not otherwise specified (NOS). The latter usually has lymphoplasmacytic features and may progress to lymphoma, Waldenström macroglobulinemia, or occasionally to LC amyloidosis; IgM MGUS, NOS is discussed in the chapter on LPL. By contrast,

IgM MGUS PC type is defined by the presence of a clonal PC population, typical myeloma IGH rearrangements in many cases, and the absence of both a clonal B-cell component and an *MYD88* mutation. This subtype of IgM MGUS may give rise in a minority of cases to IgM MM.

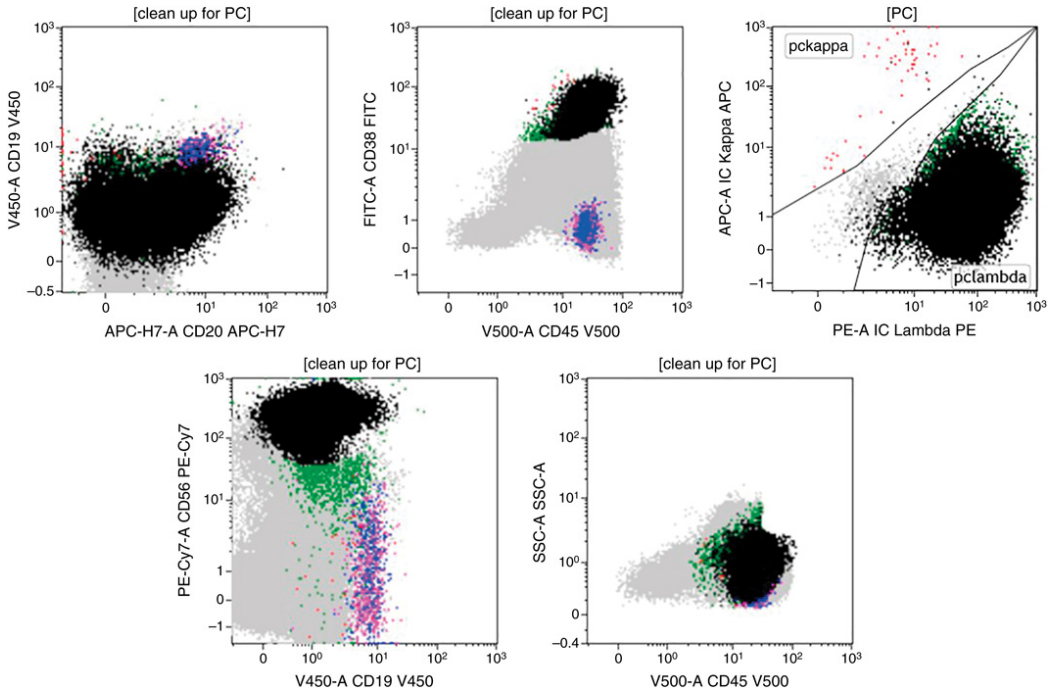

FIGURE 25-33 Distinction of CD20-positive myeloma from B-cell lymphoma.The neoplastic plasma cells (PCs) in this case have plasmacytoid morphology and express CD138, PAX5, CD20, cyclin D1, and monotypic lambda light chain by immunohistochemistry (not shown). Fluorescence in situ hybridization (FISH) confirmed t(11;14). By flow cytometry, the PCs express CD45 at a level comparable to mature B cells. They express CD20, lack CD19, express increased CD38, are lambda monotypic, and express bright CD56; this immunophenotype argues against B-cell lymphoma and supports the diagnosis of myeloma. Cell populations are identified as indicated in Figure 25-28.

Epidemiology and Etiology

MGUS is the most common monoclonal gammopathy and is found in about 3% of individuals older than 50 years and in more than 5% of those older than 70 years. The incidence of MGUS is twice as high in African Americans as in Whites, roughly paralleling the difference in incidence of MM. At least 60% of individuals with MGUS are male.

Other than advanced age and ethnicity differences, the development of MGUS has not been associated with any specific disease or predisposing clinical disorder. MGUS is typically discovered incidentally during the evaluation for an unrelated medical disorder. Transient oligoclonal and monoclonal gammopathies have been described in young patients after renal and allogeneic bone marrow transplants; there is a correlation with graft-versus-host disease in bone marrow transplant recipients.

Clinical and Laboratory Features

Other than M protein and mild increase in bone marrow PCs, there are no consistent or specific clinical findings. Abnormal laboratory studies in individuals with MGUS are usually attributable to a co-existing disease. Myeloma-associated laboratory and radiographic abnormalities are absent in MGUS by definition. M protein is found via SPE in most cases (**Fig. 25-38**). The quantity of M protein is less than 3 g/dL; the median is about 0.5 g/dL. In patients with very low-level paraproteinemia, immunofixation electrophoresis is required for detection of M protein (**Fig. 25-38**). Normal serum polyclonal Igs are decreased in about 30% of cases, and LCs (Bence-Jones protein) are present in the urine in small quantities in up to 28% of cases; in most cases, the quantity of urinary protein is less than 1

g/24 hr. In 67% to 75% of cases, the monoclonal heavy chain (HC) is IgG. IgM is found in about 15% of cases, IgA in 10% to 14%, and 2% to 3% are biclonal gammopathies; only rare cases of IgD MGUS have been reported. The LC is kappa in 54% to 63% of cases. An isolated LC is present in up to 20% of MGUS cases, which may be detected only with a serum free LC assay (see criteria for LC MGUS in **Box 25-6**).

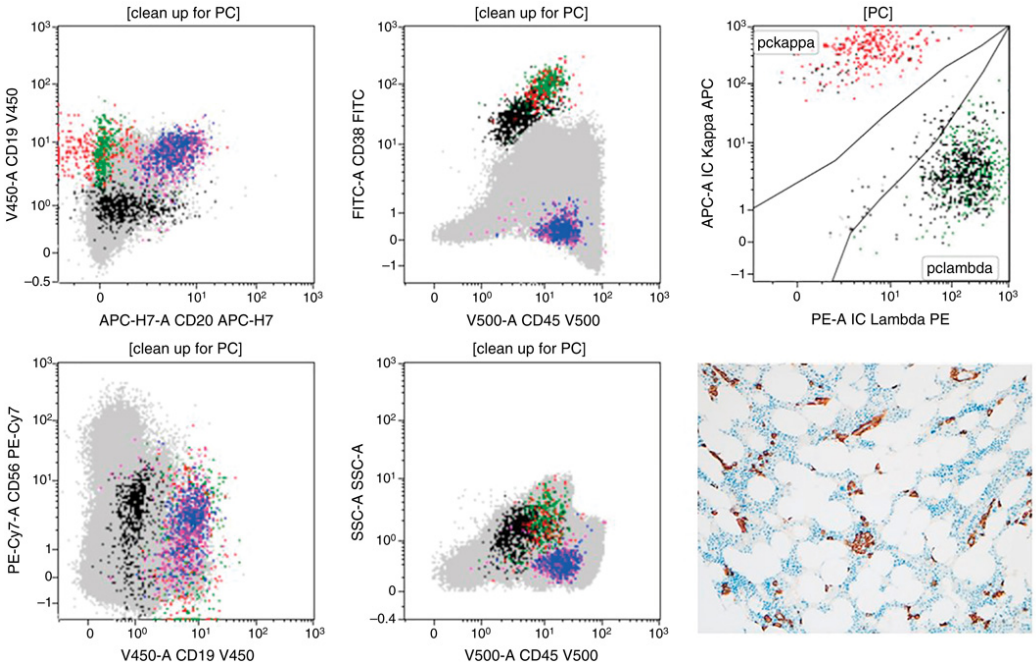

FIGURE 25-34 Light chain (LC) expression detection can vary based on method.Many practices immunophenotypically approach bone marrow diagnoses with both flow cytometry and immunohistochemistry. The patient presented for a follow-up bone marrow examination 2 years after transplant for myeloma. He had a measurable IgG-lambda M-spike. Immunohistochemistry on the bone marrow showed clusters of CD138-positive PCs, but kappa and lambda immunostains were mostly negative within the clusters (not shown). Flow cytometry showed a lambda monotypic plasma cell (PC) population that expressed CD38 (dim) and CD45 (dim), but it was mostly negative for CD19, CD20, and CD56. The t(11;14) was detected by fluorescence in situ hybridization (FISH) in a

subset of CD138-enriched PCs. The flow cytometry kappa and lambda antibodies were polyclonal, and the immunohistochemical kappa and lambda antibodies used were monoclonal. Although rare, mutated or truncated LCs in myeloma cells sometimes react unexpectedly with reagent antibodies, and combinations of polyclonal and monoclonal antibodies can be helpful in such cases. Cell populations are identified as indicated in Figure 25-28.

Blood and Bone Marrow Findings

There are no specific blood findings associated with MGUS. Rouleaux formation may be increased in patients with M-protein levels approaching a myeloma-defining level of 3 g/dL. Any blood count or other smear abnormalities are usually related to a co-existing disease.

Clonal PCs account for <10% of bone marrow cells (median, 3%), with a mild plasmacytosis in only about 50% of cases.[32,54] Morphologically, the clonal PCs usually appear mature, although mild atypia may be evident, including cytoplasmic inclusions and nucleoli. In biopsy sections, the bone marrow is usually normocellular. PCs are evenly scattered throughout the marrow or found in small clusters. Clustering of PCs is most common in cases with an increased percentage of PCs.

Immunophenotype

CD138 IHC facilitates assessment of PC number and distribution in the bone marrow biopsy. Confirmation of a monoclonal PC population with kappa and lambda stains is feasible in many cases of MGUS. However, detection of LC restriction by kappa and lambda IHC or in situ hybridization (ISH) on biopsy sections may be difficult in cases in which the clone is small or admixed with a prominent background population of normal PCs. The ratio of LC excess is less than that in MM.[161-163] When performing CD138 and LC stains, it is important they be performed on serial sections. Using inferential reasoning, one can often detect clusters of LC-restricted PCs among background polyclonal PCs in MGUS and treated MM.

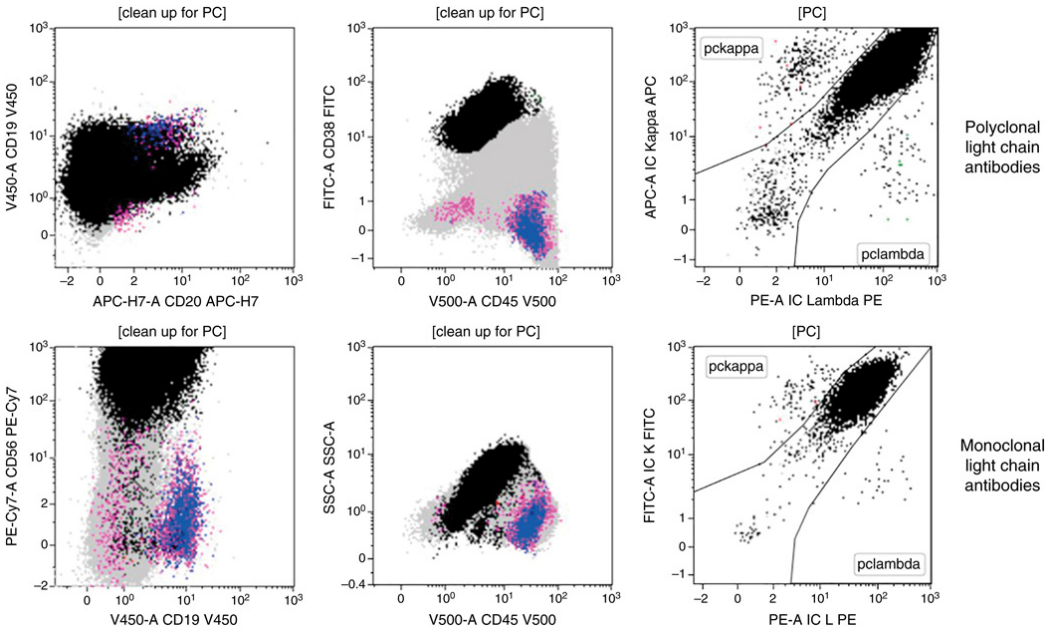

FIGURE 25-35 Dual-expressing (biphenotypic) multiple myeloma (MM).This patient presented with a lytic lesion and a large IgG-kappa M-spike. Flow cytometry identified an abnormal plasma cell (PC) population that expresses CD45 (dim), CD38, and CD56, with dim-to-absent CD19 and CD20. Using standard polyclonal cytoplasmic kappa and lambda immunoglobulin antibodies, there is poor discrimination (the PCs fall right along the diagonal of the light chain dot plot). A repeat study with monoclonal cytoplasmic kappa and lambda immunoglobulin antibodies showed similar results. On the targeted lytic lesion and bone marrow biopsy sections, kappa and lambda expression is confirmed by both in situ hybridization and immunohistochemistry. Cell

populations are identified as indicated in Figure 25-28.

Genetics

Abnormal karyotypes are rarely observed in MGUS by conventional cytogenetic studies, but numeric and/or structural abnormalities are detected by FISH in most cases of non-IgM MGUS.[10,11,13,164] The abnormalities are similar to those in myeloma, but the relative frequencies of specific aberrancies differ. Hyperdiploidy is detected in about 40% of patients with trisomies similar to that observed in myeloma.[10] Translocations targeting *IGH* (14q32) are found in nearly half of patients; the t(11;14)(q23;q32) translocation is present in 15% to 25%, t(4;14)(p16.3;q32) in 2% to 9%, and t(14;16)(q34q23) in 1% to 5%.[13,164] Deletions of 13q are present in 40% to 50% of cases.[11,164-167] Aneuploidy has been observed by image analysis in greater than 60% of MGUS cases, and most of these had numeric abnormalities by FISH analysis.[168] *KRAS* and *NRAS* mutations are less frequent in MGUS (~5%) than in myeloma (~30% to 40%), consistent with their role in disease progression.[169] Currently, no clinical correlates with chromosome abnormalities are recognized in MGUS.

Plasmacytoma

Solitary Bone Plasmacytoma

Definition and Diagnostic Criteria

Solitary bone plasmacytoma (SBP) is a localized tumor composed of clonal PCs that are cytologically, immunophenotypically, and

genetically similar to those of MM.[26,170] There is no evidence of bone marrow involvement at other sites, and clinical features of MM are lacking. The criteria for diagnosis of SBP are listed in **Box 25-7**.[2,76,79,170]

Epidemiology

SBP accounts for less than 5% of PC neoplasms.[32,171] The median age is 50 to 55 years (about 10 years younger than that for MM), and 65% to 70% of patients are male.[32,79]

Clinical Features

Most patients with SBP present with a single painful bone lesion or pathologic fracture. Soft tissue extension may result in a palpable mass.[32] Although any bone may be involved, SBP most commonly develops in bones with active hematopoiesis, particularly those of the skull, spine, pelvis, ribs, clavicle, scapula, and femur.[79,172] Involvement of long bones distal to the knee or elbow is rare.[173,174] The most common site is the spine (40% to 50%); the thoracic spine is more often involved than the lumbar or cervical spine.[32] Vertebral involvement may cause spinal cord or nerve root compression. The radiographic lesions on plain radiographs are lytic, similar to those of MM. Modern imaging techniques, such as MRI and PET-CT, are far more sensitive for the detection of bone lesions in PC neoplasms. Additional bone lesions on MRI are detected in about 30% of presumptive SBPs defined by the traditional skeletal survey.[33,175,176] As such, the diagnosis of SBP requires an MRI or CT study to confirm the solitary nature of the plasmacytoma and exclude the presence of additional osseous lesions.[33,175]

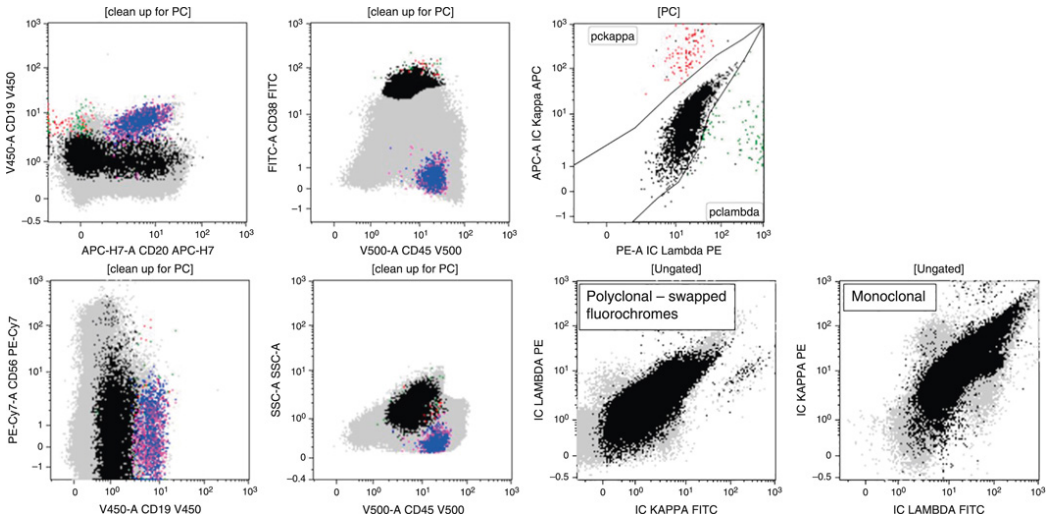

FIGURE 25-36 Nonproducer multiple myeloma (MM).This patient presented with anemia and had no detectable M protein in either the serum or urine by immunofixation; the SFLC ratio was normal. Sheets of CD138-positive plasma cells (PCs) are present in the bone marrow biopsy that lacks light chain (LC) expression by both in situ hybridization and immunohistochemistry. By flow cytometry, the PCs express CD38 with dim CD45, but they lack expression of CD19 and LC. They mostly lack CD20 and CD56. Repeat analyses using different pairs of LC antibodies (polyclonal, polyclonal with swapped fluorochromes, and monoclonal) yielded similar results. Cell populations are identified as indicated in Figure 25-28.

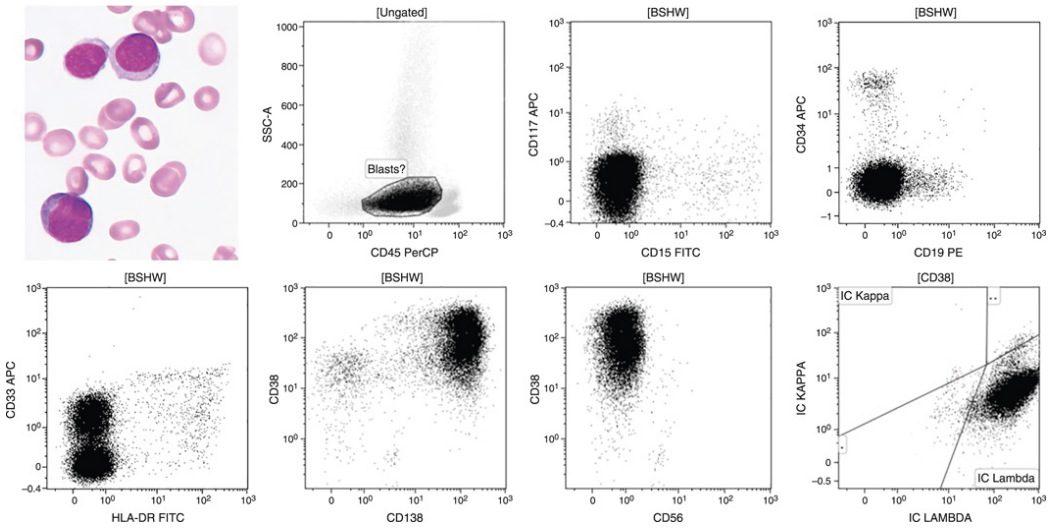

FIGURE 25-37 Plasma cell (PC) leukemia with myeloid antigen expression in a young adult.This young adult patient presented with circulating blast-like cells, and acute leukemia was suspected clinically. The neoplastic cells fall into the traditional “blast gate” in the CD45 versus SSC plot. Although the “blasts” show partial expression of the myeloid antigen CD33, they lack CD15, CD19, CD34, and CD117. The expression of CD38 and cytoplasmic CD79a without cytoplasmic MPO or CD3 prompts additional workup for PC neoplasm. The expression of bright CD38, CD138, and monotypic cytoplasmic lambda immunoglobulin light chain is confirmed; they are CD56 negative. Cell populations are identified as indicated in Figure 25-28.

Box 25-6 Diagnostic Criteria for MGUS

Intact Non-IgM M-Protein Monoclonal Gammopathy of Undetermined Significance (MGUS)

- IgG, IgA, or IgD M protein in serum, <3 g/dL
- Clonal bone marrow plasma cells (PCs) <10%
- No end organ damage (CRAB) or amyloidosis

Light Chain MGUS

- Presence of isolated free light chain with no associated heavy chain by immunofixation electrophoresis (IFE)
- Increased serum level of involved free light chain
- Abnormal serum free light chain ratio (<0.26 or >1.65)
- Urinary light chain excretion is <500 mg/24 hours
- Clonal bone marrow PCs <10%
- No end organ damage (CRAB) or amyloidosis

IgM MGUS, PC Type

- Satisfy intact non-IgM MGUS criteria
- Genetic and phenotypic studies to:
    - Identify clonal PC population with typical multiple myeloma (MM) cytogenetic abnormality
      OR
    - Identify clonal PC population without typical MM cytogenetic abnormality and lacking:
        - *MYD88* mutation

- Clonal B-cell population

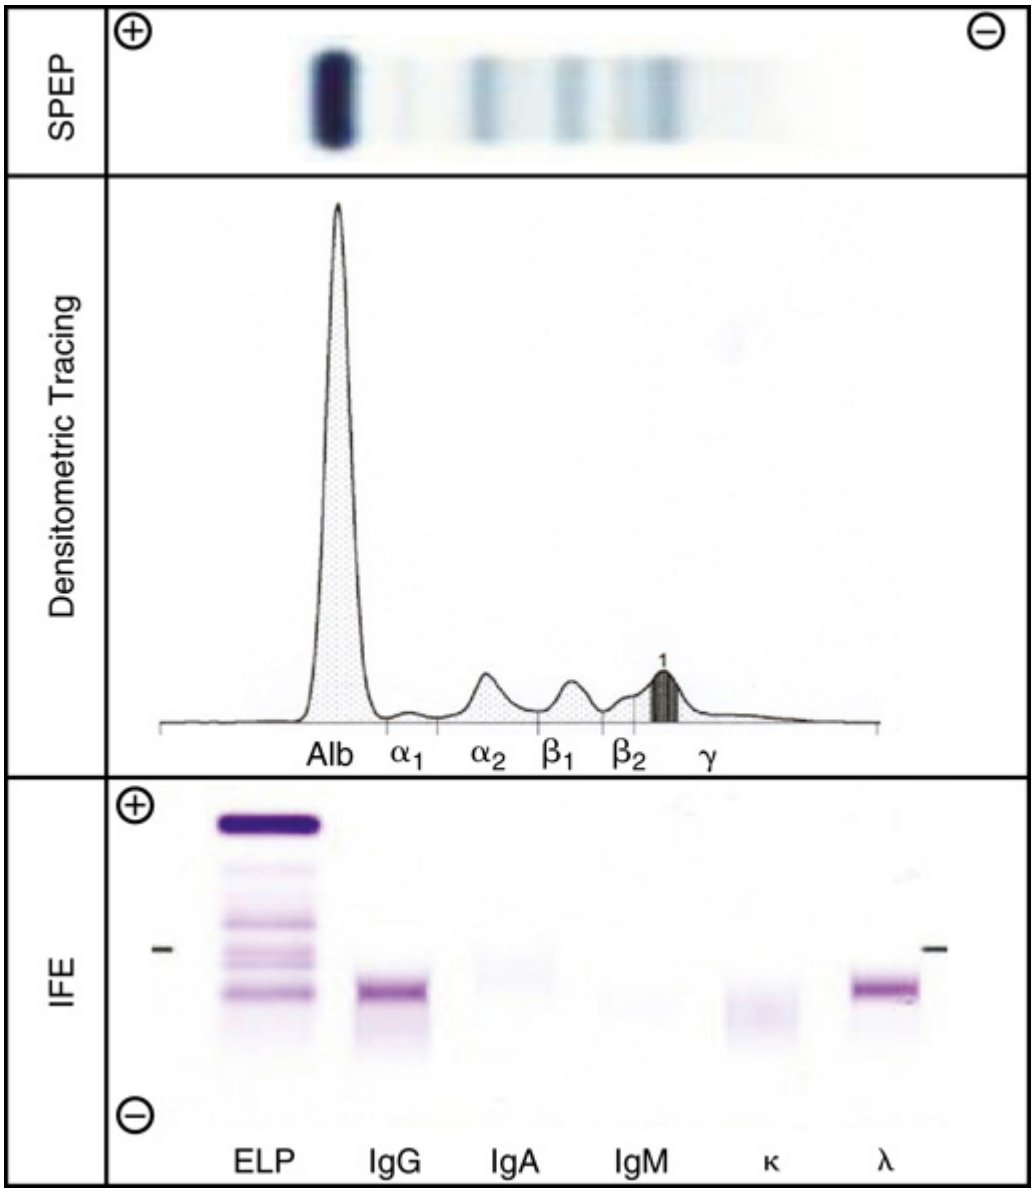

FIGURE 25-38 Serum electrophoresis in monoclonal gammopathy of undetermined significance (MGUS).The patient has no clinical, hematologic, or radiologic evidence of a PC neoplasm except a persistent, modest (0.4 g/dL), single M-protein peak *(shaded area 1 on densitometric tracing in middle panel)* by serum protein electrophoresis pattern. The M protein

was identified by immunofixation electrophoresis as IgG lambda located in the β_2-region of the electrophoretogram. Courtesy Drs. Frank H. Wians Jr. and Dennis C. Wooten.

Box 25-7 Diagnostic Criteria for Solitary Plasmacytoma

Bone or Extraosseous Plasmacytoma

- Biopsy-proven solitary lesion of bone or soft tissue consisting of clonal plasma cells (PCs)
- Normal random bone marrow biopsy with no evidence of clonal PCs
- Normal skeletal survey and CT or MRI except for the solitary lesion
- Absence of end organ damage (CRAB) attributable to a PC proliferative disorder
- No evidence of a clonal B-cell population or *MYD88* mutation

Solitary Bone Plasmacytoma With Minimal Bone Marrow Involvement

- Satisfy previously described criteria
- Clonal PCs account for <10% of bone marrow cells in random bone marrow biopsy (usually identified by flow cytometry)

Serum or urine M protein is detected in approximately half of patients, and the SFLC ratio is also abnormal in about half.[32,79,177,178] The magnitude of the paraproteinemia is significantly lower than that in MM, reflecting the relatively smaller burden of clonal PCs in SBP. Because small M-protein levels may be missed by routine electrophoresis, patients should have immunofixation studies of serum and urine to detect minimal M protein. Uninvolved Igs are quantitatively normal in most cases.[79] Blood counts, renal function studies, and serum calcium levels are normal.[32]

Morphology, Immunophenotype, and Genetics

The morphologic features, immunophenotype, and genetics of SBP are similar to those of MM (**Fig. 25-39**).

Differential Diagnosis

SBP must be distinguished from other diseases that may present with isolated lytic bone lesions. These include many types of metastatic tumors, occasional lymphomas, and other lesions of hematopoietic origin such as Langerhans cell histiocytosis and rare primary bone lesions. Biopsy of the lesion is necessary for diagnosis. SBP is not usually a diagnostic challenge, except in cases in which the neoplastic PCs have plasmablastic or anaplastic morphology and may not be recognized as plasmacytic. Rigorous IHC evaluation is critical in such cases, especially confirmation of monotypic LC expression. Solitary plasmacytoma of bone is distinguished from MM by virtue of its unifocality and absence of the clinical, laboratory, or radiographic findings typical of MM.

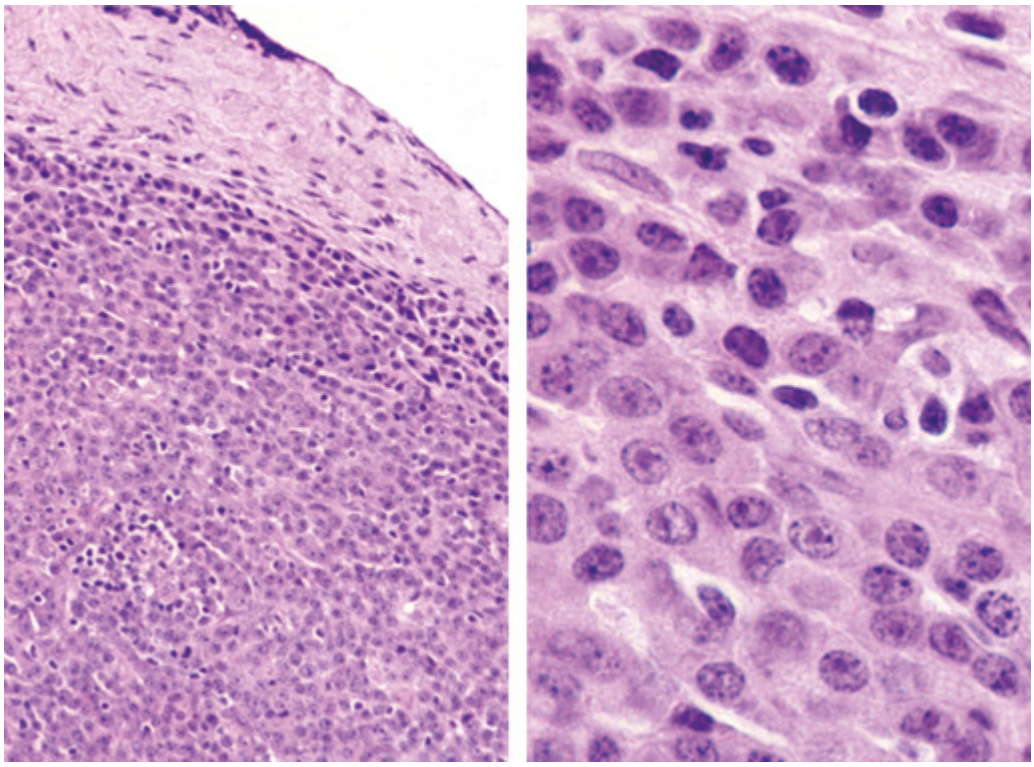

FIGURE 25-39 Solitary bone plasmacytoma.This skull lesion consists of a plasmacytoma with a fibrous border. The neoplastic cells have a somewhat immature appearance with less dense chromatin than normal PCs, and some contain nucleoli. A radiographic bone survey shows no other lesions, and a routine iliac crest bone marrow examination shows no evidence of a PC neoplasm. A minute serum IgG lambda M protein was detected by serum immunofixation electrophoresis (H&E stain).

Treatment, Clinical Course, and Prognosis

The treatment of choice for SBP is involved-field radiation, which affords long-term local disease control in 90% of cases and symptomatic relief in most cases.[178,179] M protein usually diminishes significantly after radiotherapy, and it disappears altogether in a substantial minority of patients.[180]

One-half to two-thirds of patients develop additional plasmacytomas or MM within 2 to 10 years.[32,177,178,181,182] New bone lesions, generalized marrow plasmacytosis, and increasing M protein are present with disease progression.[32,79,178,183,184] Approximately one-third of patients remain disease free for more than 10 years.[185] Many of the patients with MM have a relatively indolent course.[32]

High-risk factors for progression of SBP to MM include the presence of clonal bone marrow PCs (<10%), persistence of M protein for more than 1 year after radiotherapy, an abnormal SFLC ratio, monoclonal urinary free LCs, and flow cytometric detection of clonal PCs in morphologically disease-free bone marrow.[177,178,186,187] Patients with plasmacytoma in whom clinically occult bone marrow disease is identified by MRI are at a greater risk for progression to MM.[180,188] This finding supports the requirement for negative MRI or CT as a prerequisite for diagnosis of solitary plasmacytoma.[33,175]

Extraosseous Plasmacytoma

Definition

Solitary extraosseous/extramedullary plasmacytomas (SEPs) are localized PC tumors that arise in tissues other than bone marrow. Most appear to be biologically distinct from SBP and MM. Although

a precise origin has not been clearly defined, evidence suggests commonality between some cases of SEP and marginal zone lymphoma.[189]

Epidemiology

SEPs account for less than 5% of PC neoplasms.[76,190] The median age at diagnosis is about 55 to 60 years, and two-thirds of patients are male.[190,191]

Clinical Features

SEPs present as a localized mass lesion. About 75% of them occur in the upper respiratory tract, including the nasal passages, sinuses, oropharynx, and larynx, but they may also occur in a variety of anatomic sites including lymph nodes, parotid and thyroid gland, breast, gastrointestinal tract, central nervous system, and several other organs.[170,190,191] SEPs of the upper respiratory tract spread to cervical lymph nodes in about 15% of cases.[192]

Symptoms are usually related to the tumor mass. Patients with SEPs in the upper respiratory tract may experience rhinorrhea, nasal obstruction, and epistaxis as presenting symptoms. Approximately 20% of patients have a detectable low quantity of M protein that is most commonly IgA. Hypercalcemia, renal failure, and anemia are not present, and radiographic and morphologic assessment shows no evidence of bone marrow involvement.

Morphology

The morphologic features are similar to those of other PC neoplasms (**Fig. 25-40**).[191] A rare type of SEP has been reported that occurs in children and younger adults, is predominantly nodal, and exclusively

expresses IgA.[193] The PCs in these IgA SEPs grow in an interfollicular or diffuse pattern and are mature appearing. Bone marrow examination is recommended for adult patients with SEP to rule out overt myeloma or low-level involvement.

Immunophenotype and Genetics

The immunophenotype is similar to that of other PC neoplasms.[76,191] The PCs are clonal and exhibit LC restriction by IHC staining for kappa and lambda LCs (**Fig. 25-40**). Flow cytometric analysis on bone marrow should be performed in newly diagnosed SEP to evaluate for the presence of a low-level phenotypically aberrant PC population, as such patients appear to be at higher risk for progression to MM.[187] The genetics of SEP is similar to those of MM and include odd chromosome trisomies and *IGH* translocations, with the exception of t(11;14), which is uncommon in SEP, and possible overrepresentation of t(4;14).[76,194]

Differential Diagnosis

The differential diagnosis of SEP includes exuberant reactive PC proliferations and mature B-cell lymphomas with extreme plasmacytic differentiation, especially LPL and marginal zone lymphoma.[76,189] Exuberant reactive PC lesions are easily distinguished from SEPs in most instances by demonstrating a polytypic PC proliferation by IHC staining or flow cytometry. Distinction from lymphoma is often more difficult.

LPL consists of a mixture of clonally related PCs and lymphocytes, usually with lymphocytes predominating. In most cases, they are readily distinguished from a primary PC neoplasm, which has no lymphocyte component. However, in some LPLs, PCs are abundant

and/or the lymphocytes have an unusually plasmacytoid morphology that mimics PCs. However, there are a few features that aid in the distinction between these two lesions. In LPL, the PCs express IgM and an associated IgM M protein is present in most cases, whereas the PCs in plasmacytoma usually express IgA or IgG. More precise distinction is made by analysis for the *MYD88* L265P mutation, which is present in approximately 90% of LPL cases but absent in plasmacytoma.[195,196]

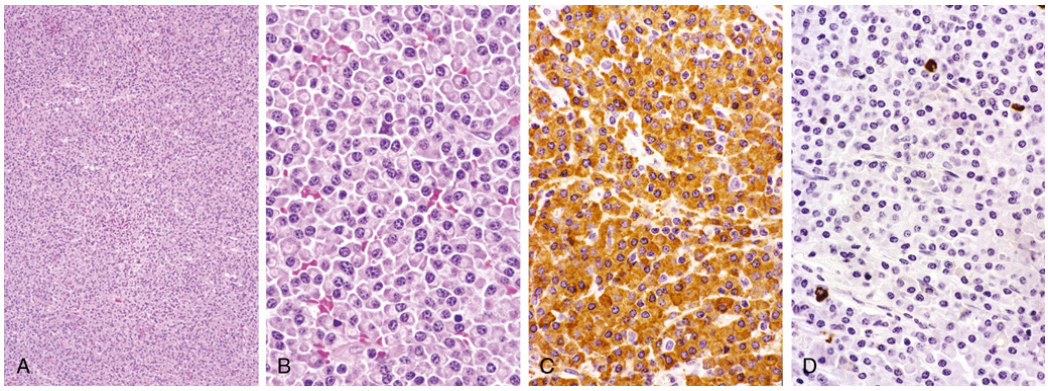

FIGURE 25-40 Extraosseous (extramedullary) plasmacytoma.**A,** In a 14-year-old girl with lupus and left cervical lymphadenopathy, the lymph node architecture is diffusely effaced by plasma cell (PC) proliferation. **B,** On higher magnification, the PCs are mature appearing. Lambda **(C)** and kappa **(D)** immunostains of the lymph node illustrated in Figure 25-36 show monotypic lambda light chain expression with only rare kappa positive cells (H&E stain; lambda and kappa light chain immunohistochemistry).

Marginal zone lymphoma with extreme PC differentiation may mimic SEP in lymph nodes or extranodal tissue. Careful morphologic examination for areas with features typical of marginal zone lymphocytes and flow-cytometric identification of clonal lymphocytes with a marginal zone immunophenotype are helpful in making the distinction.[109,189] The flow cytometric immunophenotype of the PCs may also contribute. The clonal PCs in lymphoma more frequently express CD19 (95% vs. 10%) and CD45 (91% vs. 41%) and lack CD56 (33% vs. 71%) than do those in a primary PC neoplasm.[109] In some instances, SEP and marginal zone lymphoma with extreme PC differentiation cannot be distinguished with certainty.

Treatment, Clinical Course, and Prognosis

The mainstay of therapy for SEP is surgical excision and local radiotherapy. There is local recurrence or spread to regional lymph nodes in 15% to 25% of patients.[190,197] Occasionally, there is metastasis to distant sites, and 10% to 15% progress to symptomatic MM.[190,197,198] Ten-year disease-free survival ranges from 70% to 90%.[190,197,199]

Immunoglobulin Deposition Diseases

There are two major types of Ig deposition disease: (1) primary amyloidosis and systemic LC (2) and HC deposition disease. These diseases are attributable to the synthesis and deposition of monoclonal Igs in various tissues and organs, eventually leading to organ dysfunction. This process is responsible for the frequently

aggressive clinical behavior of these disorders despite the low burden of clonal PCs.

Light Chain Amyloidosis

Systemic amyloidosis consists of three major subtypes: primary or LC (AL) amyloidosis, secondary (AA) amyloidosis, and familial (AF) amyloidosis. The latter two forms of amyloidosis consist of several variants, none of which is associated with PC dyscrasias or IGLs. Neither these nor the local amyloidoses associated with aging, endocrine amyloidosis, or the β_2-microglobulin amyloidosis of hemodialysis patients will be discussed; interested readers are referred to the review by Merlini et al., "Systemic immunoglobulin light chain amyloidosis."[200]

Definition

AL amyloidosis is a PC dyscrasia in which the clonal PCs produce a misfolded LC protein that is deposited in the viscera and ultimately results in end organ damage and dysfunction.

Pathogenesis

The synthesis of an abnormal LC by a typically small clonal PC population in the bone marrow is the defining event in AL amyloidosis. AL amyloid is composed of intact LC or fragments thereof that include the amino-terminal variable (V) region and part of the constant region.[201] Both intact LCs and fragments are present in some cases. Although all LC V-region subgroups are potentially amyloidogenic, several are notably pathogenic, including IGLV1-44, IGLV1-51, IGLV2-14, IGLV3-1, IGLV6-57, IGKV1-33, and IGKV4-1.[201,202] Several physicochemical factors may promote or inhibit the

formation of AL fibrils by influencing the aggregation of soluble LC, including polarity and charge complementarity dictated by the LC amino acid sequence, pH, and temperature.[201] Once formed, these fibrils are deposited and accumulate in tissues. AL amyloid deposition causes architectural distortion of the affected organ and toxic effects, including oxidative stress and apoptosis, all of which contributes to the end organ dysfunction that clinically defines the disease.[203] The underlying AL subtype influences, to some extent, the tissue tropism of amyloid deposition. For example, IGLV1-44 AL amyloid is associated with cardiac deposition, whereas deposition of IGLV6-57 amyloid tends to occur in the kidney.[204,205]

Epidemiology

AL amyloidosis is a rare disease, with an incidence of approximately 12 cases per million person-years in the United States[206]; however, the actual incidence of AL amyloidosis in the United States may be somewhat higher because of the underrepresentation in some clinical studies of African Americans, in whom AL amyloidosis is more common. The median age at diagnosis is 63 years, and more than 95% of patients are older than 40 years when diagnosed.[206,207] There is a slight male predominance. In most cases, only a low level of serum M protein and mild-to-moderate clonal plasmacytosis in the bone marrow are present, precluding a diagnosis of myeloma. However, concurrent AL amyloidosis and MM is found in approximately 20% of patients with AL amyloidosis.[208-210]

Clinical Features

AL amyloidosis has protean clinical manifestations, reflecting the underlying variability in tissue tropism for amyloid deposition. This

clinical heterogeneity often results in prolonged intervals between presentation and diagnosis, during which time patients experience ongoing worsening of cardiac function, and ultimately poorer clinical outcomes.[211] Patients typically present with non-specific symptoms such as fatigue and weight loss.[203,212] Bone pain, peripheral neuropathy, and carpal tunnel syndrome are the first signs of disease in some cases. Hemorrhagic manifestations (acquired factor X deficiency) and symptoms associated with congestive heart failure, nephrotic syndrome, or malabsorption are all relatively common.[212,213] Physical findings include hepatomegaly in 25% to 30% of patients and, frequently, purpura.[212] Periorbital purpura and macroglossia are classic signs associated with AL amyloidosis; however, they are present in only a small minority of patients. Edema is often present in patients with congestive heart failure or nephrotic syndrome. Splenomegaly and lymphadenopathy are uncommon.[212]

Laboratory Findings

M protein is found in the serum by protein electrophoresis in about 50% of patients, by immunofixation in more than 80%, and by a combination of immunofixation and SFLC ratio analysis in up to 99%.[212,214] IgG is most common, followed by LC only, IgA, IgM, and IgD.[202] The LC is lambda in about 70% of these.[212] The median serum M-protein level is approximately 1.4 g/dL in large clinical studies.[212,215] About 20% of patients have hypogammaglobulinemia.[212] Free LCs detected in AL amyloidosis are significantly more likely to be N-glycosylated than in other PC neoplasms, particularly in cases of kappa AL amyloidosis, suggesting

posttranslational modifications may enhance the toxicity of AL amyloid.[203,216]

Proteinuria is present at diagnosis by routine urinalysis in more than 80% of cases, and nephrotic syndrome or renal failure is found in approximately 30%; serum creatinine is >2 mg/dL in 20% to 25% of cases.[212] Hypercalcemia is occasionally present, almost always in patients with myeloma. Abnormal liver function studies are uncommon.

Hemorrhagic manifestations may result from factor X deficiency caused by the binding of factor X to amyloid proteins.[213] Hemorrhage may also be caused by deficiency of vitamin K–dependent clotting factors, fibrinolysis, disseminated intravascular coagulation, and loss of vascular integrity caused by amyloid deposition.[212,213]

Radiographic studies of bones are normal in most patients with amyloidosis. Osseous lesions are restricted to patients with co-existing myeloma and amyloidosis.

Diagnosis

A diagnosis of amyloidosis is established by detection of amyloid tissue deposits. These deposits are most often evident within blood vessel walls and along basement membranes. These may expand over time to form space-occupying lesions that impinge on or disrupt the architecture of the involved tissue. Amyloid is eosinophilic in hematoxylin and eosin (H&E)-stained sections and has an amorphous, waxy appearance, often with a characteristic cracking artifact; amyloid is weakly positive with periodic acid–Schiff (PAS) stain. Macrophages and foreign body-type giant cells may sometimes

be present at the periphery of amyloid deposits. The Congo red stain is the most commonly used technique for confirmation of amyloid in a tissue biopsy. The Congo red dye binds to the amyloid protein and produces a characteristic apple-green birefringence when evaluated under polarized light (**Fig. 25-41**).[201] Electron microscopy is rarely used today for diagnostic purposes; however, the ultrastructural findings are specific and can be confirmatory of the diagnosis. Amyloid protein consists of rigid, linear, nonbranching aggregated fibrils. The fibrils vary from 7 to 10 nm in width, have hollow cores, and are of indeterminate length.[217-219]

The frequency of amyloid deposition varies by tissue type. Bone marrow and fat pad aspirates each show positive Congo red staining in about 70% of AL amyloidosis cases; the likelihood of a positive Congo red stain increases to nearly 90% for a given patient when both tissues are evaluated.[203,212,220] Although the incidence of amyloid deposition is higher in renal and cardiac biopsies, sampling of these organs is associated with greater morbidity. Thus, the combined evaluation of bone marrow and fat pad is an appropriate first step for diagnostic confirmation in nearly all patients with AL amyloidosis.[203,220] Should these prove negative, renal or endomyocardial biopsy can be pursued in patients for whom amyloidosis is clinically suspected.

Though a positive Congo red stain indicates the presence of amyloid, confirmation of the amyloid subtype should be undertaken. In the past, this was usually achieved by IHC using antibodies that recognized the various amyloid fibril proteins, a technique that suffers from low sensitivity and specificity. Laser microdissection of the amyloid followed by liquid chromatography–tandem mass

spectrometry (LC-MS/MS) has largely supplanted IHC for amyloid typing.[221] This technique affords the unequivocal identification of the amyloidogenic protein with nearly 100% sensitivity and specificity and circumvents many of the technical issues that may be encountered with IHC-based amyloid subtyping.[214,221]

It is essential to confirm the presence of LC in the amyloid deposits in any patient with presumptive AL amyloidosis, including those in whom associated serum or urine M protein is present. AA, AF, or other types of amyloid may be incidentally present in patients with MGUS or other PC proliferative disorders.[222-224] Because the treatment of amyloidosis is directed at the underlying cause, the management of AL amyloidosis differs dramatically from that of other amyloidoses. Thus, the accurate amyloid subtyping is of paramount importance to appropriate clinical management.

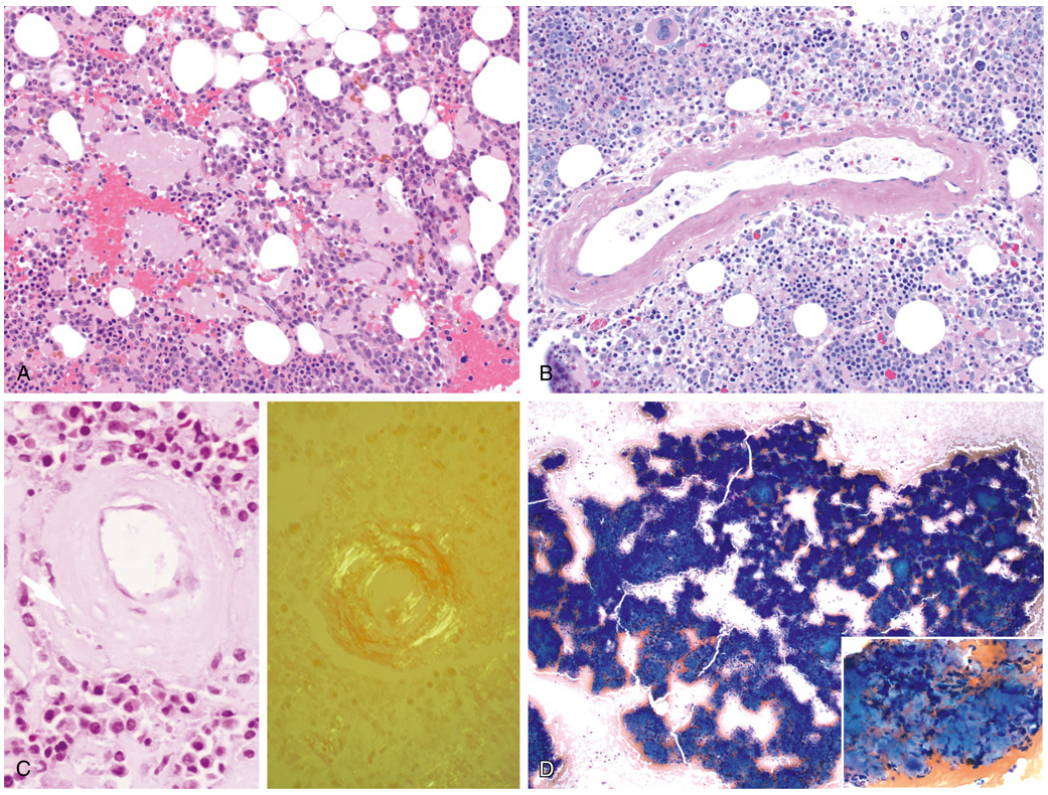

FIGURE 25-41 Primary (AL) amyloidosis involving bone marrow.**A,** Amorphous eosinophilic deposits of amyloid are present in the interstitium of the bone and may form space-occupying lesions when extensive. **B,** Blood vessel wall markedly thickened by amyloid deposits that are weakly PAS positive. **C,** Amyloid has a smudgy appearance in H&E stains *(left)* and shows typical birefringence in Congo red–stained sections examined using polarized light *(right)*. **D,** Amyloid deposits may be evident in the bone marrow aspirate and often have an angulated, geometric appearance; amorphous basophilic amyloid deposits are evident at higher

magnification *(inset)* (H&E, periodic acid–Schiff, and Wright-Giemsa stains).

Blood and Bone Marrow Findings

Blood counts are frequently normal at the time of diagnosis, but about 10% of patients present with hemoglobin levels below 10 g/dL. Leukopenia and thrombocytopenia are rare at diagnosis; about 10% of patients have thrombocytosis.[212] Abnormal blood counts are more frequent in patients with co-existing amyloidosis and myeloma. Blood smear findings are usually non-specific; rouleaux may be present in cases with a high M-protein level. Circulating PCs are observed in occasional cases, but substantial numbers of PCs are found only in the rare cases of amyloidosis associated with PCL.

Bone marrow examination should be performed in all cases of suspected AL amyloidosis. In most cases, PCs make up less than 10% of bone marrow cells in the aspirate smear at diagnosis.[212] However, PCs account for more than 20% of cells in the minority of cases in which there is concurrent amyloid deposition and myeloma. The clonal PCs may appear morphologically mature or manifest the cytologic atypia typical of MM. Vacuolated PCs resembling those seen in μ-HC disease are present in some cases.[54] With extensive amyloid deposition in the bone marrow, variably sized clumps of lightly eosinophilic-to-basophilic proteinaceous material may be evident in the aspirate smears (**Fig. 25-41**).

The bone marrow biopsy findings are variable, ranging from no identifiable abnormalities to extensive deposition of amyloid or overt myelomatous involvement. A mild plasmacytosis composed of mature-appearing PCs is the most common finding. Amyloid may be

evident in a thickened vessel wall if sufficiently large vessels are present in the biopsy or associated periosteum and soft tissue. Perivascular or interstitial amyloid deposition may be evident in the setting of more extensive involvement (**Fig. 25-41**). Occasionally, most of the bone marrow biopsy is replaced with amyloid.

Immunophenotype

The immunophenotypic abnormalities of the clonal PCs in AL amyloidosis are identical to those seen in MM and MGUS. The pathogenic PCs in AL amyloidosis show lambda LC restriction in most cases. However, assessment of LC restriction by IHC or ISH performed on the bone marrow biopsy may be problematic in those cases in which normal PCs are abundant and may outnumber the amyloidogenic PC clone.[217,225,226] Phenotypic evaluation by flow cytometry, including confirmation of LC restriction, is preferable in such cases.

Genetics

The karyotypic aberrations in AL amyloidosis are similar to those of MM, with some differences in the relative frequency of specific lesions.[227-229] It should be noted that t(11;14) is present in 40% to 60% of AL amyloidosis cases, a frequency two to three times higher than in MM.[228-230] Other common chromosomal abnormalities include deletion of chromosome 13 or 13q14, trisomy of single chromosomes, and gain of chromosome 1q21. Some of these have adverse prognostic effects. For example, t(11;14) is predictive of a poor response to bortezomib-based chemotherapy and as such is a negative prognostic factor in AL amyloidosis.[231] However, patients

with t(11;14) AL amyloid appear to respond well to therapies that incorporate newer agents such as daratumumab and venetoclax.[232]

Differential Diagnosis

The differential diagnosis of AL amyloidosis includes MM with amyloidosis, other types of amyloidosis (e.g., AA, AF, and LC and HC deposition diseases), and rarely, other disorders. MM with amyloidosis is distinguished from amyloidosis by the frequency of PCs in the bone marrow, the clinical findings, and the results of laboratory and imaging studies. Clinical findings and history are important in the distinction of AL amyloidosis from the other types. However, the diagnosis of any amyloidosis is predicated on the detection and subtyping of amyloid deposits by LC-MS/MS, as previously described.[214,221]

A Congo red stain or electron microscopic studies will differentiate AL amyloid from LC and HC deposition diseases. Finally, prominent serous fat atrophy in the bone marrow, sometimes referred to as gelatinous transformation, may histologically resemble extravascular amyloid deposition (**Fig. 25-42**). A Congo red stain, the clinical history, and laboratory findings readily distinguish between these two processes.

Treatment and Prognosis

Modern therapy for AL amyloidosis is predicated on elimination of the amyloid-producing PC clone, thereby abrogating further production of LC and tissue deposition of amyloid. Early diagnosis is critical, as it increases the likelihood the patient will tolerate subsequent therapy and improves the odds of reversing end organ damage.[233] The appropriate diagnosis of amyloidosis is

unfortunately often delayed months or even years because of its rarity and non-specific clinical features. As a result, most patients with AL amyloidosis present with some degree of cardiac and renal impairment, and some 80% are not suitable candidates, at least initially, for some of the more aggressive therapies such as autologous hematopoietic stem cell transplantation (HSCT).[2,3,4]

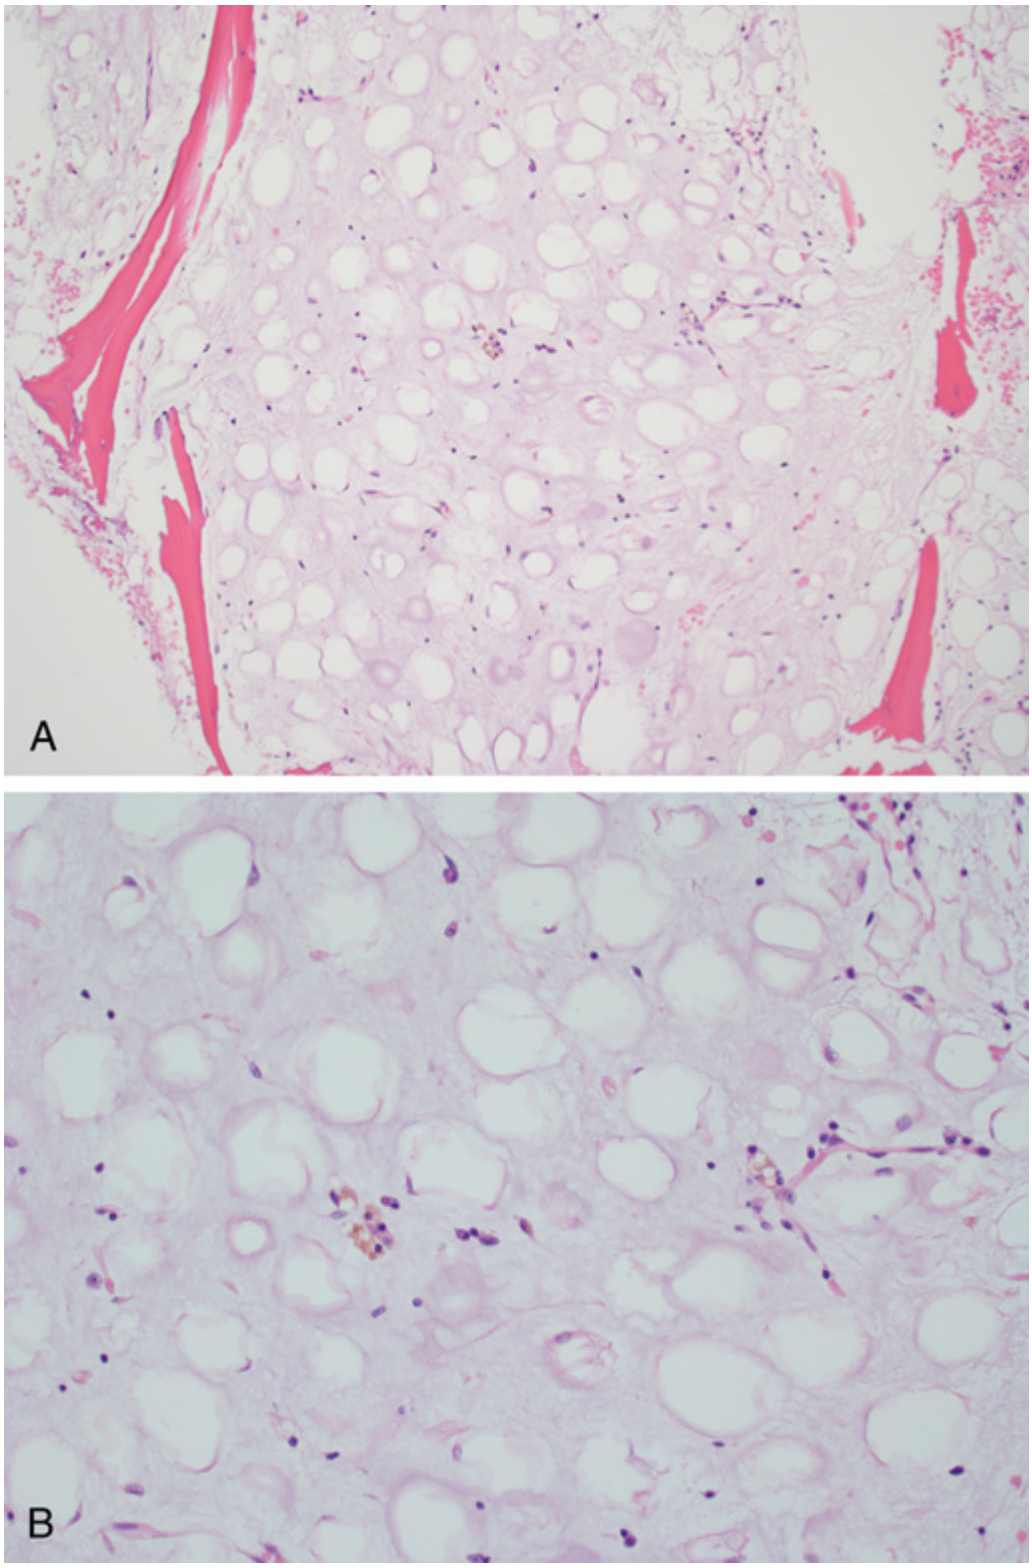

FIGURE 25-42 Bone marrow with serous atrophy of fat resembling amyloid.**A** and **B,**

When extensive, the amorphous appearance of serous atrophy of fat may mimic amyloid deposition. Most cases of serous fat atrophy occur in individuals with severe malnutrition (bone marrow biopsy; H&E stain).

The advent of new, less toxic agents, including the proteasome inhibitor bortezomib and daratumumab, which targets CD38, has had a profound effect on therapy for AL amyloidosis. Dara-CyBorD (daratumumab, cyclophosphamide, bortezomib, dexamethasone) induces excellent rates of hematologic response, very good partial/complete responses, and significantly higher renal and cardiac response rates than regimens lacking daratumumab; it is now the frontline therapy for eligible patients.[232,235] A rapid and deep response to therapy is an important predictor of survival. It is important to note that inclusion of daratumumab overcomes the negative prognostic effect of t(11;14) in AL amyloidosis treated with previous bortezomib-based regimens.[235] The role of autologous HSCT is evolving and is now primarily reserved for patients who achieve suboptimal hematologic or organ responses to these newer therapeutics.[232] The safety profile of immunomodulatory agents, such as thalidomide and lenalidomide, has limited their use in patients with AL amyloidosis.[236]

Despite these therapeutic advances, prognosis in AL amyloidosis is still largely dictated by the extent of organ dysfunction at presentation. After initiation of therapy, improvement in cardiac, renal, and hepatic function typically lags several months to a year or more behind the hematologic response, highlighting the critical need for ongoing supportive care in patients with AL

amyloidosis.[213,237,238] The role of solid organ transplantation in patients with irreversible cardiac or renal damage is controversial, but it may be appropriate in select patients.[236]

The SFLC level combined with two cardiac biomarkers, cardiac troponin-T and N-terminal pro-B-type natriuretic peptide (NT-proBNP), are the basis of the widely used Mayo staging system for AL amyloidosis.[239] Elevation of none or one or more of these parameters delineates four stages, which has prognostic effects. Patients with stage I and stage II disease have median overall survivals of 94 and 40 months, respectively, which is far superior to those of patients with stage III and stage IV disease, in whom the median survival is 14 and 6 months, respectively.[239] Present therapies have improved survival and quality of life for patients with AL amyloidosis, especially those diagnosed early with low-stage disease. For patients with high-stage disease, however, the prognosis remains poor, with significant cardiac involvement being the major determinant of outcome. However, within an advanced cardiac stage III cohort, evaluation of NT-proBNP and blood pressure may identify patients with significantly better outcomes.[233] Other factors associated with poor outcome are clonal PCs at myeloma levels (>10%), high baseline free LC levels, and elevated β_2 microglobulin.[219,239]

Systemic Light Chain and Heavy Chain Deposition Diseases

Definition

The monoclonal Ig deposition diseases (MIDDs) are PC or, rarely, lymphoplasmacytic neoplasms characterized by the secretion and

deposition of an abnormal LC or HC chain, or both, in tissues, causing organ dysfunction.[2,26] The abnormal LC deposits neither form amyloid β-pleated sheets nor bind Congo red, and they lack an amyloid P-component. This group of disorders includes LC deposition disease (LCDD), HC deposition disease (HCDD), and LC and HC deposition disease (LHCDD), of which LCDD is the most common.[240-246]

Epidemiology

These are very rare diseases. Most patients are middle aged or elderly, and there is a variable male predominance.[241-243,245,247,248] LCDD often develops in association with MM (40% to 65% of cases) or MGUS.[243,245,249] Some cases are idiopathic or occur in association with a lymphoid neoplasm.[242,243,245]

Pathophysiology

The synthesis and deposition of a structurally altered LC or HC, resulting from either point mutations or deletions, is the central pathogenetic event in MIDDs. The primary defect in LCDD is the acquisition of mutations of the variable region of the IGL gene, with kappa LC of Vκ4 type overrepresented.[242,243,250] These mutations may result in replacement of polar amino acid residues by hydrophobic ones or aberrant N-glycosylation, thereby altering the solubility of the resulting LC, which ultimately results in its tissue deposition.[243,251] Deletion of the first constant domain, CH1, is a consistent finding in HCDD, a mutation that disrupts the association of the resulting IGH to the Ig binding protein, BiP, leading to premature secretion.[243,252] The variable regions in HCDD also

contain amino acid substitutions, which result in an increased propensity for tissue deposition.[240,243,247,251]

Clinical and Laboratory Findings

Patients manifest symptoms of organ dysfunction resulting from systemic Ig deposition. The deposition of the aberrant Ig is most prominent on basement membranes and elastic and collagen fibers. Kidneys are most frequently affected. Nearly all patients with LCDD present with renal manifestations, most commonly nephrotic syndrome and/or renal failure.[245,248] Symptomatic extrarenal deposition occurs less frequently in LCDD, most commonly involving the heart, liver, and peripheral nerves, but is rare in HCDD.[243,245,253] Diffuse or nodular pulmonary involvement has also been reported.[254-256] Γ HC deposition is most common in HCDD, but rare cases of α, μ, and δ HCDD have been reported.[257-260] HCDD of IgG3 or IgG1 isotypes is associated with hypocomplementemia, as these subclasses most readily fix complement.[241,261] M protein is detected by SPE or IFE in approximately 85% of cases. An abnormal FLC level is present in virtually all LCDD cases.[243,249]

Morphology

The bone marrow burden of clonal PCs in LCDD and HCDD ranges from that of MGUS to symptomatic MM[243,245,249]; co-existent MM is less common in HCDD.[241,243] LPL, marginal zone lymphoma, and chronic lymphocytic leukemia are rarely encountered.[243,262]

Deposition of LC or HC is mostly found in renal biopsies but can be observed in bone marrow and other tissues in some cases. The Ig deposits consist of amorphous eosinophilic material that is neither

amyloid nor fibrillary and stains negatively with Congo red. LCDD is diagnosed in renal biopsies via fluorescent anti-LC antibodies and electron microscopy.[243-245,261] Light microscopic evaluation of the renal biopsy typically shows nodular sclerosing glomerulonephritis. LC deposits in the glomerular and tubular basement membranes have a refractile eosinophilic appearance and are most frequently kappa type. Confirmation of LC deposition is usually achieved by immunofluorescence, which reveals the characteristic smooth, ribbon-like linear peritubular deposits of monotypic Ig along the outer edge of the tubular basement membrane. These deposits are nonfibrillar, powdery, and electron-dense on ultrastructural examination, with absence of a β-pleated sheet structure by radiographic diffraction.[244,245,261] Although uncommon, PCs are found in the vicinity of Ig deposition within visceral organs in some cases.[242,254]

Immunophenotype and Genetics

Kappa LC is expressed in 68% to 80% of LCDD cases, with overrepresentation of IGKV4-1, in contrast to AL amyloidosis, in which lambda LC expression predominates.[243,245,249] Depending on their frequency, the clonal PCs may exhibit an aberrant kappa-to-lambda ratio by LC IHC on bone marrow sections.

The underlying genetic abnormalities in LCDD and HCDD are poorly characterized, but those with co-existent MM presumably have aberrancies similar to those of other myelomas.

Differential Diagnosis

Amyloidosis is the main consideration in the differential diagnosis of LCDD and HCDD. These disorders are distinguished from one

another based on their clinical features, Congo red and immunofluorescence staining, and ultrastructural and mass spectrometric analysis of the aberrant Ig deposits (see previous discussion in this chapter's section on the diagnosis of AL amyloidosis).

Treatment and Prognosis

Therapy is predicated on elimination or reduction of the clonal Ig-producing PCs to control deposition of the aberrant Ig in tissues, similar to the approach used for AL amyloidosis. The addition of daratumumab to drug regimens appears to have significant benefit in the few reported cases.[263,264] Supportive measures to preserve organ function, especially renal function, are important components of patient management.[245,253] Autologous HSCT is effective for controlling the disease and reversing renal dysfunction in some patients with LCDD.[265] The reported median overall survival for patients with LCDD varies widely, ranging from 4 years in older studies to 14 years in more recent reports,[245,248] a difference that likely reflects the effects of newer therapeutic agents such as bortezomib and daratumumab and improvements in supportive care. Deep hematologic responses to therapy are critical to preserving renal function and preventing disease recurrence in renal allografts.[248] Response to therapy can be monitored by evaluation of the SFLC levels.

Plasma Cell Neoplasms With Associated Paraneoplastic Syndrome

POEMS Syndrome

Definition

Polyneuropathy, **o**rganomegaly, **e**ndocrinopathy, **m**onoclonal gammopathy, and **s**kin lesions (POEMS) syndrome is a paraneoplastic disorder usually associated with an osteosclerotic PC neoplasm.[266-269] Several other features are frequently present that are not included in the POEMS acronym. These include Castleman disease, papilledema, edema and serous effusions, thrombocytosis, erythrocytosis, and elevated serum vascular endothelial growth factor (VEGF).[270] Most patients do not present with all of the manifestations. The diagnostic criteria are indicated in **Box 25-8**.[270]

Epidemiology, Etiology, and Pathogenesis

POEMS syndrome is a rare disease, accounting for 1% to 2% of PC neoplasms. Men are affected slightly more commonly than women (1.4:1 male-to-female ratio). The median age at diagnosis is about 50 years.[266] Many cases have been reported in Asia.[268]

The pathogenesis of POEMS syndrome is not well defined, but the dysregulated expression of proinflammatory cytokines, in particular VEGF, is a consistent feature of this disorder.[271-273] Despite this, VEGF-targeted therapy has shown variable efficacy in POEMS syndrome, raising questions about its pathologic role in this disorder.[274-276] Although VEGF may influence localized paracrine effects that are not easily targeted therapeutically, this cytokine may instead simply represent a marker of disease rather than a central pathologic driver of it. The pathophysiologic connection among POEMS syndrome, osteosclerotic myeloma, and Castleman disease is not well understood.

Box 25-8 Criteria for the Diagnosis of POEMS Syndrome

Mandatory

- Polyneuropathy
- Monoclonal plasma cell (PC) proliferative disorder

Major (One Required)

- Castleman disease
- Sclerotic bone lesions
- Elevated serum vascular endothelial growth factor (VEGF)

Minor (One Required)

- Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy)
- Extravascular volume overload
- Endocrinopathy
- Skin changes
- Papilledema
- Thrombocytosis

Although the serum level of VEGF is elevated in POEMS syndrome in nearly all cases, the origin of VEGF remains controversial. VEGF is produced by both the clonal PCs and the background polyclonal PCs in POEMs. However, the clonal PCs in MGUS and MM express comparable levels of *VEGFA* mRNA; VEGF protein production was

not assessed.[277] Because of the high frequency of certain motifs in the lambda variable-joining (VJ) segments in POEMS syndrome, it has been speculated that the aberrant autocrine/paracrine secretion of VEGF may be triggered by the clonal lambda LC through a molecular mimicry mechanism involving the chaperonin HSP90α.[278]

Clinical Features

The diagnosis of POEMS syndrome is often delayed as a result of its rarity and the complexity of clinical findings. The diagnosis of POEMS syndrome relies on fulfillment of mandatory, major, and minor criteria (**Box 25-8**).[270] The mandatory criteria include polyneuropathy and a monoclonal PC proliferation associated with M protein. The neuropathy is demyelinating, ascending, and symmetric and affects both sensory and motor function. The M protein is usually either IgA or IgG with a lambda LC in more than 95% of cases and is present at low levels (median 1.1 g/dL).[266] In addition to the mandatory criteria, at least one of three major criteria and one of six minor criteria are required for diagnosis. Several of these are usually fulfilled. The serum VEGF level is markedly elevated in most cases and correlates with disease activity.[279] Sclerotic bone lesions are present in approximately 95% of cases.[266,270] Single sclerotic lesions are detected by radiographic studies in about half of cases, and more than three lesions in one-third.[266] Two-thirds of patients with lymphadenopathy have the PC variant of Castleman disease, and most of these have a clonal PC proliferative disorder.[266] A rare Castleman variant of POEMS syndrome that lacks an associated clonal PC proliferation, but with

many of the other paraneoplastic features, has been described.[270,280]

Three of the original pathologic findings in the POEMS acronym are presently considered minor criteria for diagnosis, but each is found in at least half of cases. Endocrinopathy, most frequently hypogonadism or thyroid disease, is found in more than two-thirds of patients. Skin changes, mostly hyperpigmentation and hypertrichosis, also occur in more than two-thirds of cases, whereas organomegaly is present in about 50% of patients.[270] Other minor criteria include extravascular volume overload manifesting as peripheral edema, ascites, or pleural effusion (30% to 85%), papilledema (~40%), thrombocytosis (~75%), or polycythemia (~15%). Other common but non-specific clinical findings include weight loss, fatigue, clubbing, bone pain, and arthralgias. Hypercalcemia, renal insufficiency, and pathologic fractures, all relatively common in MM, are rare in patients with POEMS syndrome.

Morphology

There are no specific morphologic changes in blood smears from patients with POEMS syndrome. Blood count abnormalities include thrombocytosis in about 75% of patients and polycythemia/erythrocytosis in 12% to 19%.[266,269,270] Blood counts are normal in some patients, and overall, cytopenias are less frequent in patients with POEMS syndrome than in those with MM.

An osteosclerotic plasmacytoma, either as a single lesion or multiple lesions, is the typical pathologic finding in POEMS syndrome. Directed bone biopsies are often required for diagnosis

because of the focal nature of the lesions. The presence of bone trabeculae with marked osteosclerosis is a characteristic feature of these plasmacytomas (**Figs. 25-43 to 25-45**). Paratrabecular fibrosis is common with entrapped PCs that may appear elongated as a result of distortion by bands of connective tissue.[26] In random bone marrow biopsies away from the plasmacytoma, the marrow is usually normocellular, and the median number of PCs is usually less than 5% but may exceed 50% in patients with extensive marrow disease.[269,281] In patients with disseminated disease, the PCs are interstitially distributed or present in variably sized clusters. Lymphoid aggregates rimmed by monotypic or polytypic PCs may be evident in the bone marrow biopsy. Megakaryocyte hyperplasia is frequently present, often with atypical cytologic features and clustering similar to those in myeloproliferative neoplasms; reticulin fibrosis is absent.[281]

Immunophenotype

A monoclonal PC population is detected in most cases either by flow cytometry or IHC.[281] The clonal PCs are identified in a background of polytypic PCs in most cases. The clonal PCs in POEMS syndrome show the same immunophenotypic aberrancies as observed in other PCNs.[281] The clonal PCs are lambda LC restricted in approximately 95% of cases and express IgA or, less frequently, IgG by IHC.[266,269,281]

Genetics

From the few published analyses, the cytogenetic findings in POEMS syndrome are similar to those of myeloma, albeit with different frequencies of individual abnormalities.[282,283] IGH rearrangements

are present in 22% to 45% of cases, mostly commonly t(11;14). The frequency of hyperdiploidy is variable in the few reported analyses.[277,282] Monosomy 13/deletion of 13q occurs at a frequency similar to that of myeloma.[282,283] No significant correlation between cytogenetic aberrancies and clinical features has been defined.[283]

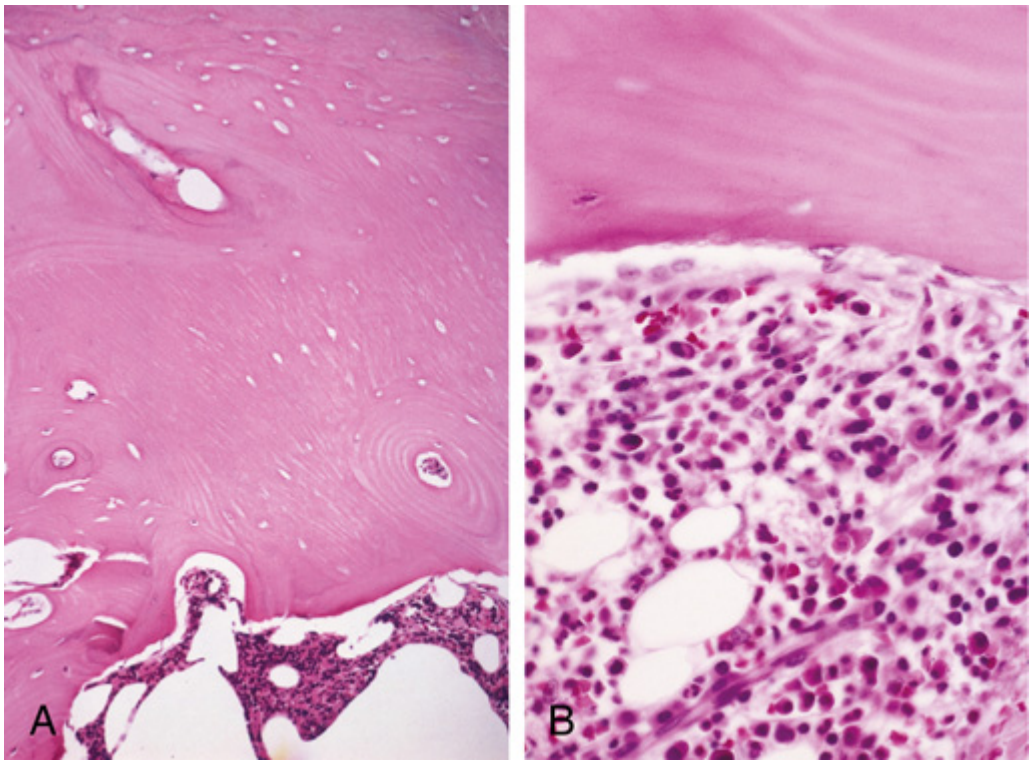

FIGURE 25-43 Osteosclerotic lesion in POEMS syndrome.Biopsy of an osteosclerotic vertebral lesion in a patient with polyneuropathy and serum IgA lambda M protein. **A,** Low magnification shows markedly thickened bone. **B,** A plasma cell proliferation adjacent to the bone is appreciated at higher magnification, and osteoblasts line the bony surface (bone marrow biopsy; H&E stain).

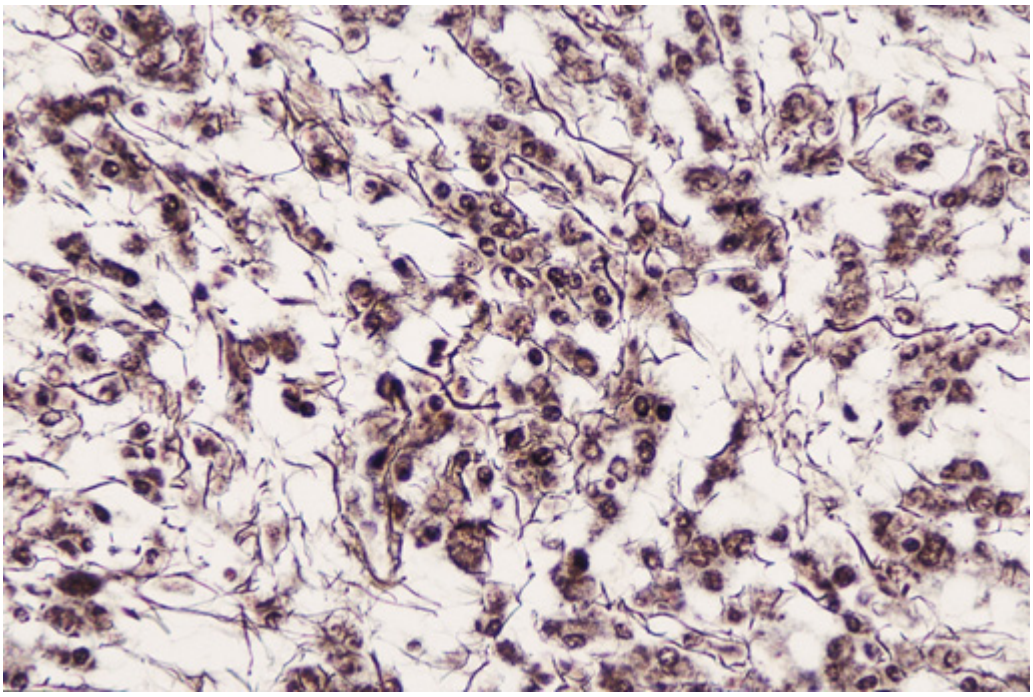

FIGURE 25-44 Reticulin stain of a PC lesion in POEMS syndrome.There is a moderate increase in reticulin with fibers weaving around clusters of PCs (Wilder's reticulin stain).

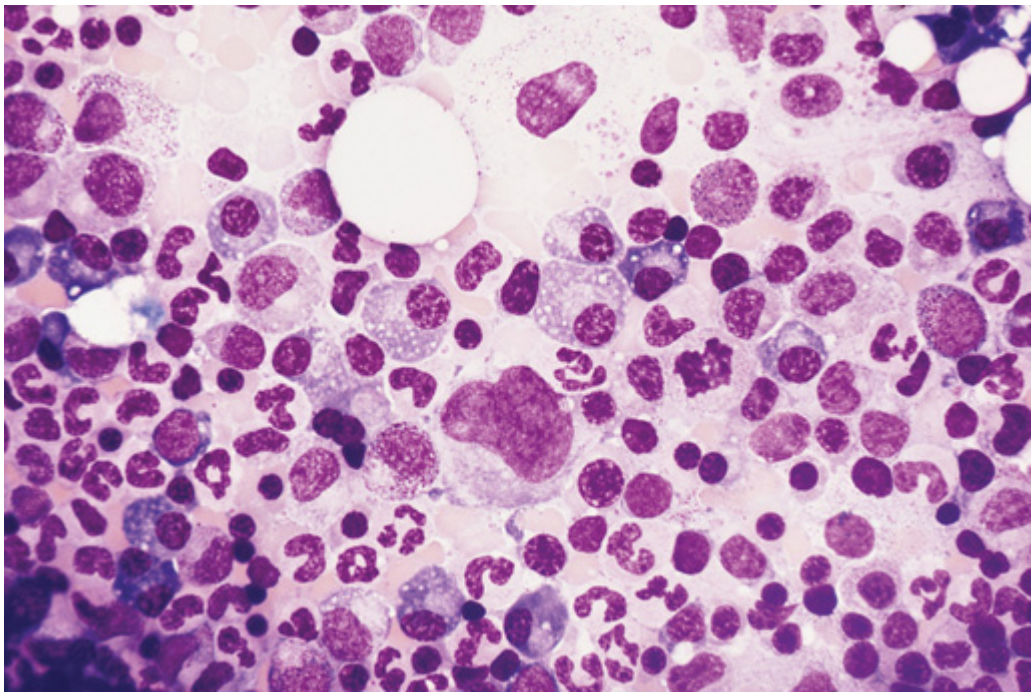

FIGURE 25-45 POEMS syndrome with multiple osteosclerotic bone lesions.There are increased plasma cells, which appear relatively mature; many contain cytoplasmic vacuoles (bone marrow aspirate; Wright-Giemsa stain).

As previously mentioned, the PCs in nearly all POEMS syndrome cases show lambda LC restriction. In such cases, there is very restricted use of lambda variable domains, with the clonal lambda sequence containing IGLV1-40 or IGLV1-44 in 83% of cases and rearranged to the IGLJ3*02 segment in 100% of cases.[278,284,285] Further, sequencing analysis has revealed distinctive mutational patterns in the VJ segment in POEMS syndrome, e.g., replacement of the threonine 38 residue in 100% of cases using an IGLV1-44 segment.[278] These restricted lambda variable domain and mutational patterns have obvious potential as diagnostic molecular markers in POEMS syndrome.

Differential Diagnosis

The diagnosis of POEMS syndrome is often problematic because of its rarity and protean clinical manifestations. Diagnosis requires the integration of biopsy findings with clinical data and the results of laboratory and imaging studies. If the primary focus is on any single paraneoplastic manifestation to the exclusion of the larger clinical picture, diagnosis can be delayed. In the early stages of disease, other polyneuropathies and clonal PCNs must be excluded, especially MGUS, asymptomatic myeloma, and solitary plasmacytoma. When POEMS syndrome is considered according to clinical findings, it can be confirmed by radiographic assessment, VEGF testing, and directed or random bone marrow biopsy.[270] Familiarity with the bone marrow changes in POEMS syndrome is important. The findings in random bone marrow biopsies can mimic a myeloproliferative neoplasm in some cases.[281]

Treatment and Prognosis

Radiotherapy is appropriate for patients with isolated bone lesions and no evidence of clonal PCs in the routine bone marrow examination, a therapeutic approach similar to that for solitary bone plasmacytoma. Improvement or resolution of the paraneoplastic symptoms occurs over several months, and in some cases, apparent cure can be achieved.[270] For patients with disseminated disease, systemic therapy is required with adjuvant radiotherapy to reduce any large bone lesions. The same agents used to treat MM are used in POEMS syndrome. Autologous HSCT is also an option.[270]

Overall, POEMS syndrome has a more favorable prognosis than MM or AL amyloidosis. The course is generally chronic and

progressive but with a median overall survival up to 165 months, and 60% to 90% of patients survive 5 years or more.[270,286] Patients with localized disease and candidates for radiation therapy fare best. Clinical factors associated with shorter survival include older age, pulmonary hypertension, extravascular fluid overload, fingernail clubbing, and respiratory symptoms.[270,286] The most common causes of death are cardiorespiratory failure and infection.[266]

TEMPI Syndrome

Definition

The **t**elangiectasias, elevated **e**rythropoietin/erythrocytosis, **m**onoclonal gammopathy, **p**erinephric fluid collection, and **i**ntrapulmonary shunting (TEMPI) syndrome is a rare PC neoplasm with prominent paraneoplastic features with about 30 cases reported to date.[287,288] Like POEMS syndrome, the manifestations of TEMPI syndrome appear to be related to a clonal PC proliferation and its M protein. The specific clinical and laboratory findings, however, are mostly distinct from those of POEMS syndrome.

Etiology, Epidemiology, and Genetics

The etiology, pathogenesis, and prevalence of TEMPI syndrome are largely unknown. Most patients present in their 30s or 40s—both males and females, with no obvious ethnic or geographic skewing of cases.[287] Because of some degree of clinical overlap with other disorders, TEMPI syndrome may be somewhat more common than is suggested by the few reported cases.

The pathogenesis of TEMPI syndrome is poorly understood. Whole genome sequencing in a single case showed the absence of

typical myeloma-associated initiator and driver mutations, including *IGH* translocations, hyperdiploidy, chromosome 13 deletion, and *RAS* gene mutations.[289] Interestingly, duplication of chromosome 22q11.23 was detected, which encompasses the *MIF* gene, which encodes a proinflammatory cytokine with angiogenic biological activity. Analysis of *MIF* mRNA and MIF protein levels in serum and bone marrow revealed significant elevations of MIF in TEMPI syndrome compared with control and MM cases, suggesting a possible pathophysiologic role for dysregulated MIF expression in TEMPI syndrome. In addition, the consistent elevation of serum erythropoietin (EPO) levels suggests the possibility of perturbation of the HIF1-α mediated oxygen sensing pathway in TEMPI syndrome, although the mechanism for this is unknown.[287]

Clinical and Laboratory Features

The onset of TEMPI syndrome is insidious, with slowly progressive symptoms. Most patients present with erythrocytosis and telangiectasias and subsequently develop intrapulmonary shunting and hypoxia. The erythrocytosis is driven by a progressive and marked increase in serum EPO levels. The telangiectasias are usually most prominent on the face, upper back, chest, and arms; the lower extremities are generally spared. The perinephric fluid collects between the kidney and renal capsule, is clear and acellular, and has a composition similar to serum. Venous thrombosis or intracranial hemorrhage is reported in some patients.[288,290,291] M protein is detected in all patients, but there is no clear association with a particular antibody isotype or LC.[288,292-295] The SFLC ratio and

absolute levels are within normal limits in many patients.[291] Unlike POEMS syndrome, VEGF levels are not increased.[294]

Morphology

Bone marrow examination is often performed for unexplained erythrocytosis or an abnormal protein electrophoresis. There does not appear to be any specific blood or bone marrow morphologic finding in TEMPI syndrome, but erythrocytosis and marrow hypercellularity caused by erythroid hyperplasia are recurrent findings.[294] In one patient, erythroid and megakaryocytic atypia was described, and reactive lymphoid lesions were present in another.[294] Bone marrow clonal PCs are usually present at MGUS levels (<10%).[291,294] However, mild-moderate plasmacytosis with more than 10% PCs has been reported in a few patients, one of whom was diagnosed with SMM. No patient reported to date has fulfilled the criteria for symptomatic MM. Mildly atypical PCs are usually present, including ones with cytoplasmic vacuolization.[292,294]

Immunophenotypic Features

The immunophenotypic features for only a few TEMPI syndrome cases have been reported; the clonal PCs appear to manifest the same immunophenotypic aberrancies found in other PCNs.[287,289] In most cases, the PCs are IgG kappa restricted.[291]

Differential Diagnosis

Differential diagnosis considerations for TEMPI syndrome include other causes of erythrocytosis, mostly polycythemia vera, and POEMS syndrome. The marked elevation of EPO and lack of a *JAK2* V617F mutation largely exclude polycythemia vera. Secondary

erythrocytosis is rarely associated with EPO levels as high as in TEMPI syndrome and can usually be distinguished by associated clinical manifestations. POEMS syndrome with erythrocytosis and skin changes may partially mimic TEMPI syndrome. VEGF levels are characteristically elevated in POEMS syndrome but are not increased in TEMPI syndrome.[294]

Treatment and Prognosis

In the limited reported cases, the main therapeutic approach in TEMPI syndrome has been directed at reduction of the clonal PCs and M protein. Complete or partial resolution of symptoms has been achieved with the proteasome inhibitor bortezomib or a bortezomib-based regimen followed by autologous HSCT.[292,294,296] Complete resolution of symptoms with single-agent daratumumab has been reported in two patients who had partial response or disease recurrence after bortezomib-based therapy.[295] The serum EPO level also provides a good index of therapeutic response in patients with TEMPI syndrome.[287,294] The efficacy of therapy aimed at ablation of the neoplastic PC clone substantiates the central role that the clonal PCs and M protein play in the pathogenesis of this paraneoplastic syndrome. Timely recognition of the disease and prompt initiation of treatment before development of advanced symptoms is key to a good clinical outcome.

Pearls and Pitfalls

Pearls

- Diagnosis of PCNs requires integration of clinical, morphologic, radiographic, and laboratory findings.
- Serum and urine immunofixation electrophoresis is the gold standard for characterizing the HCs and LCs of monoclonal Ig and for detection of small quantities of M protein.
- FLC analysis is highly sensitive for detecting minute quantities of M protein. It is important in monitoring patients and a prognostic indicator in all categories of PCN.
- IHC stains are valuable for quantitative assessment of plasma cells in bone marrow biopsies, for identification of a monoclonal plasma cell proliferation, and in distinguishing myeloma from other neoplasms.
- Flow cytometry should be performed for initial characterization of the neoplastic PC clone and to monitor for MRD.
- Cytogenetic and molecular genetic findings are the strongest predictor of prognosis for MM and should be performed in all cases for risk stratification.
- Patients with MGUS must be monitored indefinitely for evolution to a malignant PCN. The type and size of M protein and FLC ratio are significant predictors of MGUS disease progression.
- The diagnosis of SBP is predicated on sensitive imaging techniques, such as MRI or PET-CT, to exclude MM from the differential diagnosis.
- A high index of suspicion is necessary to avoid missing bone marrow involvement by AL amyloidosis, as amyloid deposits

may be subtle, the extent of plasmacytosis is typically low, and the clonal PCs are often cytologically indistinguishable from normal PCs.

- AL amyloidosis can often be diagnosed based on the findings in a bone marrow biopsy and fat pad aspirate, obviating the need in most patients for endomyocardial or renal biopsies, procedures associated with greater risk of morbidity.
- Laser microdissection of the amyloid followed by liquid chromatography–tandem mass spectrometry is now the gold standard for molecular typing of amyloid deposits.

Pitfalls

- Low levels of monoclonal Ig, as commonly seen in IgD, IgE, and LC-only myeloma, may be undetectable by SPE. These can be missed if FLC analysis is not performed.
- Focal myelomatous bone marrow lesions may be missed in random biopsies. In patients with macrofocal myeloma, the extent of plasmacytosis in intervening marrow may be similar to that of MGUS.
- Low-level disease may go undetected if immunophenotyping by flow cytometry or IHC is not performed.
- Myeloma/MGUS-related cytogenetic changes may be undetectable by FISH performed on routine bone marrow specimens unless combined with cytoplasmic Ig staining to highlight PCs for analysis or by performing FISH on PC-enriched samples.

- SEP may be difficult to distinguish from lymphoplasmacytic and MALT lymphoma with extreme plasmacytic differentiation.
- Failure to perform amyloid typing may lead to a misdiagnosis of AL amyloidosis in a patient with unrelated MGUS and lead to inappropriate treatment.
- PCNs with a paraneoplastic syndrome may be deceptive, causing delayed diagnosis. Familiarity with the manifestations of POEMS and TEMPI syndromes is necessary for an appropriate index of suspicion.

CONCLUSION

Definition

Nodular lymphocyte-predominant B-cell lymphoma (NLPBL), also known as nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL), is an indolent germinal-center (GC) B-cell neoplasm, usually with a nodular growth pattern, comprising a minority of large neoplastic cells with multilobated nuclei, the so-called "popcorn" or lymphocyte-predominant (LP) cells (formerly called *L&H cells [lymphocytic and/or histiocytic Reed-Sternberg cell variants]*), and a majority of reactive lymphocytes and histiocytes. Though previously considered a form of Hodgkin lymphoma, it has long been recognized that NLPBL shows clear and consistent histologic, epidemiologic, immunologic, and genetic differences from classic Hodgkin lymphoma (CHL). Molecular data have confirmed these differences and shown greater similarity to B-cell non-Hodgkin lymphomas (NHL). The Clinical Advisory Committee (CAC) for Lymphoid Malignancies recommended the term NLPBL to reflect this in the 2022 International Consensus Classification (ICC).[1]

SYNONYMS AND RELATED TERMS

The 5th edition of the World Health Organization (WHO) Classification[2] retains the term nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) as in the revised 4th edition, and this term can be used when needed so as not to interfere with ongoing clinical trials.

Historical Background

The original classification of NLPBL as a Hodgkin lymphoma was in 1947, when Jackson and Parker identified a subtype termed *Hodgkin's paragranuloma*.[3] After describing a nodular variant of

paragranuloma,[4] the so-called “Rye classification” combined lymphohistiocytic nodular and diffuse types into one class designated LP.[5,6] Work by Poppema and coworkers on the histology, immunophenotype, and epidemiology of these cases indicated that they represented an entity separate from CHL.[7-9] A more formal distinction from CHL was proposed by the International Lymphoma Study Group in the Revised European American Lymphoma (REAL) classification[10] and adopted by the WHO[11] under the term NLPHL. In 2021, the CAC introduced the term NLPBL and grouped this entity with B-cell NHLs based on molecular findings including data suggesting a pathologic and biological continuum between NLPBL and T-cell/histiocyte-rich large B-cell lymphoma (THRLBCL).[1]

Epidemiology

NLPBL accounts for 3% to 8% of Hodgkin lymphomas in Western countries.[12-14] In older series, one-third to half of the cases may in fact have been lymphocyte-rich (LR) CHL. NLPBL occurs in all age groups, with a peak incidence in the fourth decade, in contrast to a peak incidence in the third decade for the nodular sclerosis subtype of CHL (**Fig. 26-1**).[9,15] NLPBL shows a male predominance of 2.4:1, different from the slight female predominance in nodular sclerosis CHL. There are no significant differences between the epidemiologic features of cases that are exclusively nodular and those with prominent diffuse areas.

Familial cases of NLPBL have been reported.[16,17] A Finnish population-based study indicated a high familial risk in families with *NPAT* or *TET2* germline alterations.[18-20] First-degree relatives of NLPBL patients had a standardized incidence ratio for NLPBL of 19,

compared with 5.3 for CHL and 1.9 for NHL. Familial NLPBL affected males and females equally, in contrast to the male predominance of NLPBL overall. The reasons underlying the familial risk for NLPBL are unknown but may include both genetic and environmental factors, including infectious etiologies.

Immune responses also distinguish NLPBL from CHL. Variants in the *KLHDC8B* gene have been found in familial CHL but were not definitely associated with familial NLPHL.[21] Conversely, NLPBL has been reported in two children with Hermansky-Pudlak type 2 syndrome, a primary immune deficiency associated with *AP3B1* mutations.[22] These patients were found to have reduced NK and NK T-cell subsets, suggesting a possible role of effector cell defects in NLPBL. The risk of Hodgkin lymphoma in young adults decreases with an increasing number of C alleles at position −174 in the interleukin-6 promoter.[23] A significant excess of G alleles at this position was observed in young adults with NLPBL.[24] A truncating germline mutation in *NPAT,* a gene adjacent to *ATM* that encodes a nuclear protein associated with cell-cycle regulation, has been shown to segregate with NLPBL in an affected Finnish family; another germline variant in *NPAT* was found in several other patients with NLPBL or CHL.[25]

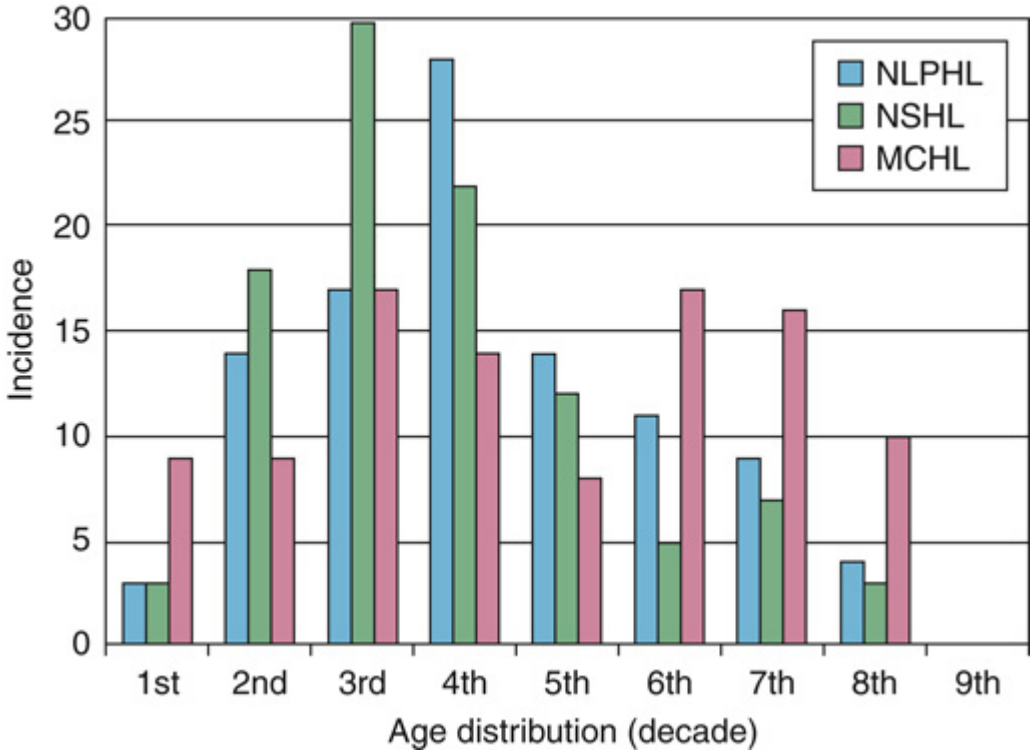

FIGURE 26-1 Age distribution of nodular lymphocyte-predominant B-cell lymphoma (NLPBL, denoted in the figure as NLPHL; n = 206), nodular sclerosis classic Hodgkin lymphoma (NSHL; n = 398), and mixed cellularity classic Hodgkin lymphoma (MCHL; n = 293) in a case series from the lymph node registry in Kiel, Germany, 1978. Note the peak incidence of NLPBL in the fourth decade versus the peak incidence of NSHL in the third decade.

There are several indications that Hodgkin lymphoma may have an infectious cause,[26,27] and there is extensive evidence that Epstein-Barr virus (EBV) plays a role in a major subset of CHL.[28,29] Some studies have found evidence of EBV-positive NLPBLs, especially in developing countries,[30-34] whereas other studies found

only negative cases.[35,36] Though inclusion of lymphocyte-rich classic Hodgkin lymphoma (LRCHL) cases in older reports[37] and early EBV infection as seen in developing countries[33] might explain rare EBV-positive NLPBL in some series, two North American studies have confirmed the existence of true EBV-positive NLPBLs.[38,39] Data suggest little geographic difference in clinicopathologic features, including EBV positivity.[40] EBV-positive LP cells typically co-express CD30 and demonstrate latency type II. In some cases, the LP cells are only partially EBV positive and/or EBV positivity is also seen in occasional bystander lymphocytes, suggesting EBV may not be a primary driver of NLPBL lymphomagenesis.[41] A possible role of other viruses, including human herpesvirus 6, has been studied[42] but has not been demonstrated to date. Although CHL is seen with increased frequency in patients infected with human immunodeficiency virus (HIV), a risk for NLPBL has not been observed.[43] An antigen screen approach identified an RNA polymerase, RpoC, derived from *Moraxella catarrhalis* as a frequent antigenic target of the B-cell receptor of IgD-positive LP cells; activation induced by RpoC was additive with the *Moraxella* superantigen MID/hag.[44] These patients frequently presented with HLA haplotypes HLA-DRB1*04 and HLA-DRB1*07, indicating a role for cognate T-cell help.[45]

Clinical Features

Patients usually present with isolated lymphadenopathy of long duration. There is frequent involvement of cervical and axillary nodes, with less frequent inguinal or femoral nodal involvement. Mediastinal NLPBL is an unusual finding (7%).[15,46] The most

frequently involved primary extranodal sites include the tonsil, parotid gland, and soft tissue. The liver and spleen are common extranodal sites of high-stage node-based disease. Splenic involvement is associated with variant histologic patterns and has an increased risk for transformation to DLBCL.[47,48] B symptoms are uncommon and are found in only 10% of patients.[46] Bone marrow involvement by NLPBL is extremely rare (2.5%) and is associated with aggressive clinical behavior and poor prognosis; the frequency of bone marrow involvement is increased in NLPBL with variant histologic patterns.[49,50]

NLPBL typically presents as early-stage disease, with slow progression and an excellent outcome with standard therapy. Approximately 20% of patients have advanced disease at the time of presentation.[15] Recurrences develop in a relatively high percentage (~21%), regardless of original clinical stage, and multiple recurrences (27%) are not uncommon.[15] In 65% of cases, the recurrence is local or regional; in 23%, the recurrence is in a different region; and in 12%, the disease is generalized. Frequently (in 67%), the histopathologic growth pattern at relapse remains identical to that at initial diagnosis, and the time to relapse is related to the growth pattern, with nodular cases relapsing up to 16 years after initial diagnosis.[51]

NLPBL is not known to transform to CHL, though clonally related NLPBL and CHL have been reported.[7,52] In contrast, transformation to DLBCL has been reported to occur in 3% to 14% of cases[7,47,53] and is associated with variant histologic patterns of NLPBL.[54] Less commonly, NLPBL and DLBCL are seen in the same site as composite lymphoma.[55,56] Transformation to DLBCL and the

relationship between NLPBL and THRLBCL are discussed later in this chapter.

Morphology

Histologic Patterns

At low magnification, complete obliteration of the lymph node architecture is usually evident. In some cases, a compressed rim of normal lymphoid tissue with reactive follicles is present in the periphery of the node, usually sharply demarcated from the tumor tissue. Fan and associates[57] described six immunoarchitectural patterns of NLPBL, given letter designations A-F: (A) “classic” nodular pattern, B-cell-rich; (B) serpiginous/interconnected nodular pattern; (C) nodular with prominent extranodular LP cells; (D) nodular with T-cell–rich background; (E) diffuse pattern (THRLBCL-like); and (F) diffuse, “moth-eaten,” with B-cell–rich background. The histologic pattern, particularly in cases with variant patterns, should be reported. A mixture of patterns in a single biopsy is more commonly observed than a single, pure pattern. At the 2021 CAC conference, it was recommended that the immunoarchitectural patterns be segregated into two groups for clinical purposes because of the prognostic effect of variant histology.[1,58] Grade 1 would include typical cases (Fan patterns A, B, and C). These patterns show retained nodular architecture and prominent small B cells. Grade 2 would include variant patterns (patterns D, E, and F). Cases with grade 2 histology might benefit from treatment similar to those of DLBCL, though clinical features also influence treatment decisions, and additional study is needed. Of note, a study found that pattern C cases were associated with an intermediate clinical stage between

patterns A/B (mostly early/intermediate stage) and patterns D/E (mostly advanced stage)[59]; additional study of the prognostic significance of pattern C is warranted.

Neoplastic cells are found both within and outside the macronodules (**Fig. 26-2**).[7,8] The nodularity created by loose aggregates of follicular dendritic cells (FDCs) is generally easily appreciated in routine H&E (hematoxylin and eosin) slides, but it may be visualized by immunohistochemistry. The nodules vary in size, but they are mostly large. A diffuse growth pattern can be seen focally; rarely, it may predominate.

The predominant cell population in the nodules is small lymphocytes. The presence of histiocytes and LP cells leads to a "moth-eaten" appearance (**Fig. 26-3**). In some cases, groups of epithelioid cells may form a ring in a circular pattern around the nodules (**Fig. 26-4**).

Scattered FDC nuclei can be identified; in some cases, multinucleated, Warthin-Finkeldey–type giant cells are seen. These are most likely FDC multinucleated variants (**Fig. 26-5**). The cellular composition of the nodules may vary within the same lymph node: nodules with a predominance of lymphocytes can be seen together with nodules showing a large proportion of epithelioid histiocytes.

Occasionally, only a small number of LP cells are present; more often, they can be found with little difficulty. In rare cases, they form large clusters and are the most conspicuous cell type within some nodules[60]; the few published cases with nodules of syncytial LP cells had good outcomes.[60,61] Although typical LP cells have characteristic cytologic features, neoplastic cells resembling classical

Hodgkin and Reed-Sternberg (HRS) cells also may be seen.[7,37] The identification of classical HRS cells should always prompt careful immunohistochemical evaluation to exclude the possibility of LRCHL with a nodular pattern. However, in some cases of NLPBL, the LP cells may mimic classical HRS cells while retaining the immunophenotype of LP cells. Conversely, cases of otherwise typical NLPBL may express CD30 and/or CD15.[62-64]

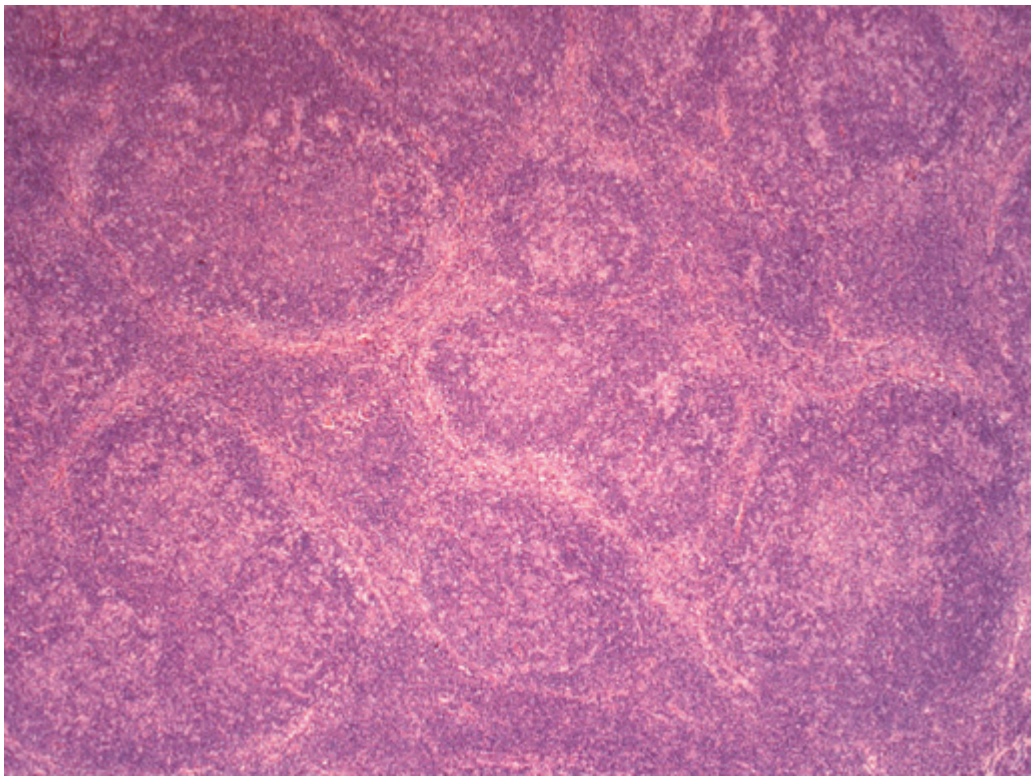

FIGURE 26-2 Nodular lymphocyte-predominant B-cell lymphoma. The normal lymph node architecture is replaced by nodules containing predominantly small lymphocytes.

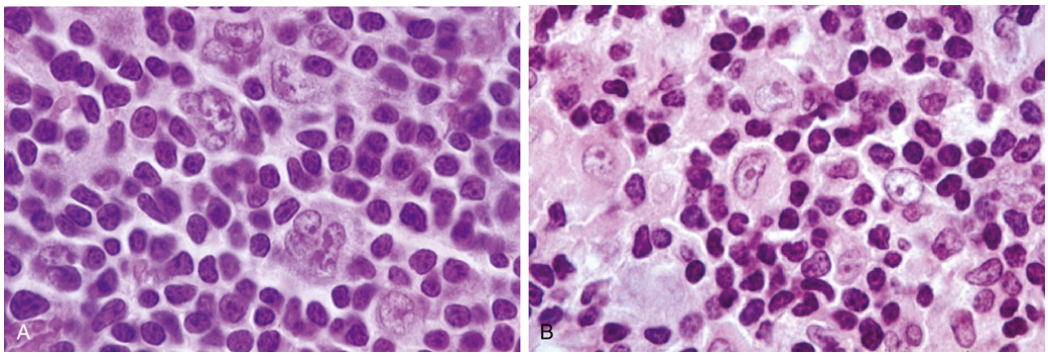

FIGURE 26-3 **A,** Several lymphocyte-predominant cells with multilobated nuclei and a small rim of cytoplasm can be seen. **B,** Several histiocytes with prominent cytoplasm are present. Both cell types are surrounded by small lymphocytes.

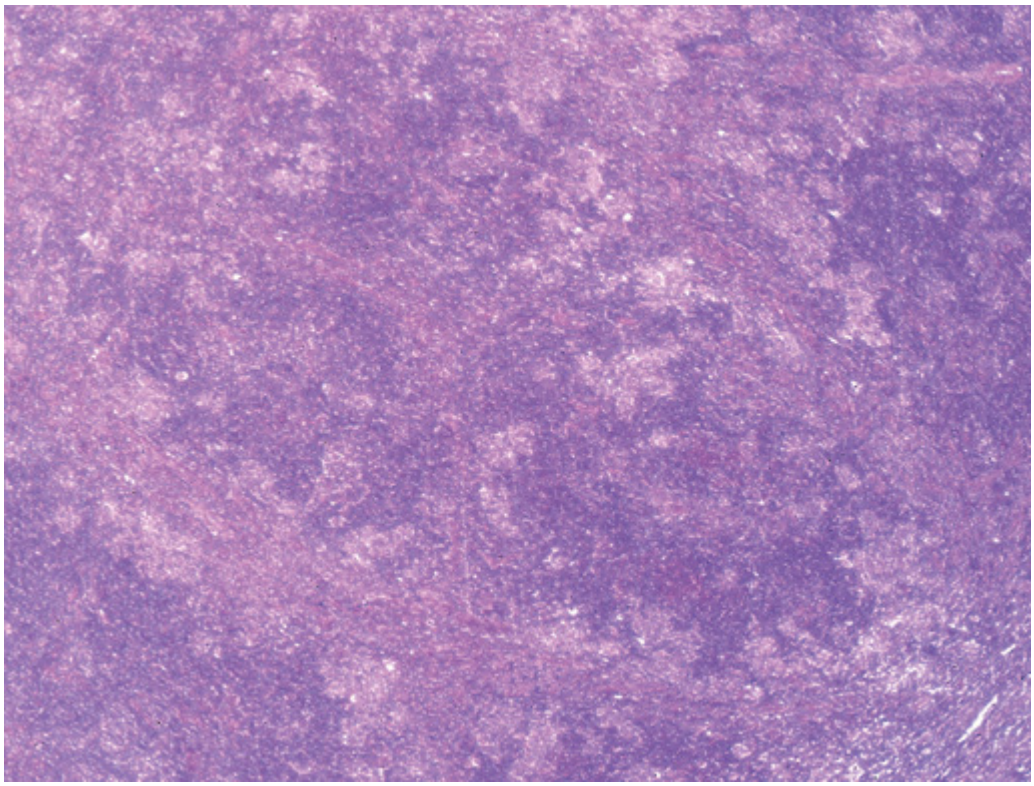

FIGURE 26-4 The nodules of nodular lymphocyte-predominant B-cell lymphoma may be surrounded by clusters of epithelioid histiocytes.

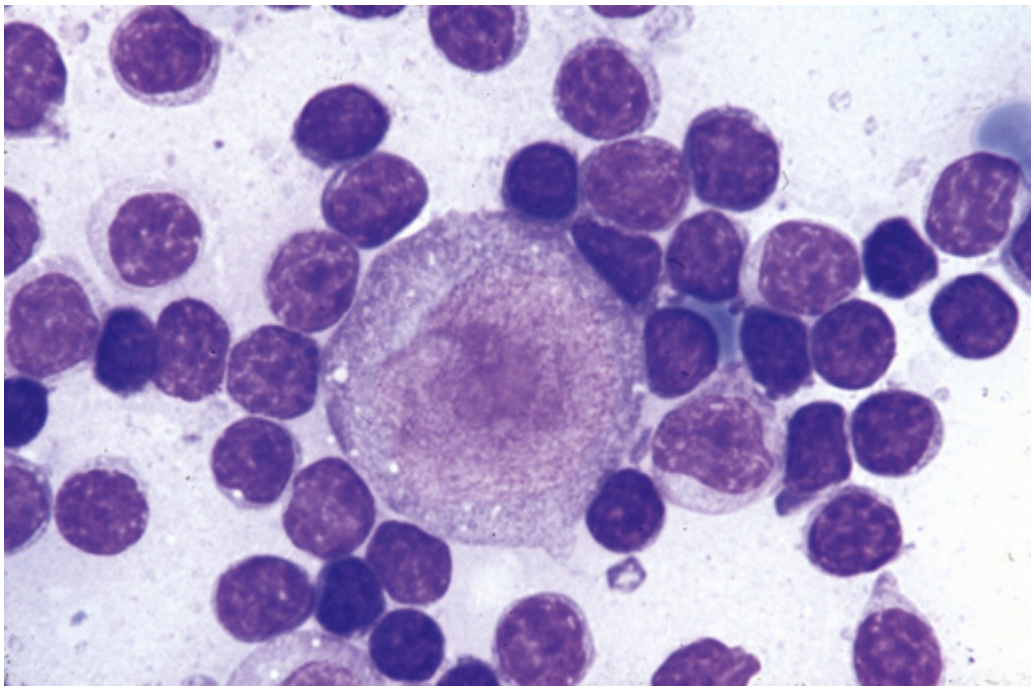

FIGURE 26-5 Imprint of a lymph node with nodular lymphocyte-predominant B-cell lymphoma showing an LP cell surrounded by rosetting activated lymphocytes.

The compressed internodular areas contain small lymphocytes and high endothelial venules. Plasma cells and eosinophils are characteristically scarce or absent. In some cases of NLPBL, there is a nodular sclerotic stromal reaction, particularly in large nodal masses. Because a documented history of long-term nodal enlargement is available in some of these cases, it is possible that this represents a chronic-phase tissue reaction to the NLPBL.

Distinction of the diffuse (THRLBCL-like) pattern of NLPBL (Fan pattern E[57]) from THRLBCL has led to some controversy over whether these are actually distinct processes[58]; they likely reside within the same spectrum. An argument in favor of retaining the pattern E terminology is that pattern E may co-exist with other

histologic patterns in the same case. In a review of a large case series by the European Task Force on Lymphoma, only 2% lacked nodular areas.[65] In the largest series of NLPBL cases reviewed, only 7 cases out of 219 (3%) closely resembled THRLBCL.[37] Recurrence of NLPBL with a purely diffuse pattern has been described[66] and has been designated THRLBCL-like transformation of NLPBL. The presence of numerous LP cells outside the nodules may predict progression to a THRLBCL-like pattern.[57] This pattern is also encountered as nodular aggregates involving the white pulp of the spleen.

Table 26-1

Major Diagnostic Features of Nodular Lymphocyte-Predominant B-Cell Lymphoma

Feature	LP Cells	Background Cells
Morphology	Nuclei larger than centroblasts, hyperlobated nuclei, medium-sized nucleoli, sparse basophilic cytoplasm	Follicles with predominantly small lymphocytes, together with histiocytes and LP cells; "moth-eaten" appearance
Immunophenotypic features	$CD45^+$, $CD20^+$, $CD15^-$, $CD30^-$, $BCL6^+$, AID^+, $BSAP^+$, $OCT2^+$, $BOB.1^+$, $PU.1^{+/-}$, $MUM1^{+/-}$, $T\text{-}bet^{+/-}$, $HGAL^+$, $BCL2^-$, $p53^-$, $CD10^-$, $CD138^-$, EBV^-	Predominantly $CD4^+$ T cells; $CD4^+$, $c\text{-}MAF^+$, $CD57^+$, $PD1^+$ T-cell rosettes around LP cells are present; low ratio of $TIA\text{-}1^+$ to $CD57^+$ T cells

Feature	LP Cells	Background Cells
Genetic and molecular findings	Clonal immunoglobulin gene rearrangements; ongoing mutations; *BCL6* rearrangements in half of cases; *BCL2* translocation usually not detected	Polyclonal B cells and T cells

AID, Activation-induced cytidine deaminase; *EBV,* Epstein-Barr virus; *HGAL,* human germinal-center–associated lymphoma protein; *LP,* lymphocyte predominant.

The major diagnostic features of NLPHL are summarized in **Table 26-1**.

Lymphocyte-Predominant Cells

LP cells are large cells, with nuclei larger than those of normal centroblasts (**Fig. 26-5**). Owing to their complex lobation, the term *popcorn cells* has been widely used. The nucleoli are medium-sized, generally basophilic, and smaller than those of classical HRS cells. The cytoplasm of LP cells is relatively sparse. In Giemsa-stained

tissue sections and in Wright-stained imprints or smears, the cytoplasm may be moderately basophilic.

Immunophenotype

Lymphocyte-Predominant Cells

Lymphocyte-Signaling Molecules

LP cells stain with antibodies to CD45, in contrast to most classical HRS cells (**Table 26-2**).[67,68] There is consistent staining for pan–B-cell markers such as CD20 (**Fig. 26-6A**), CD22, and CDw75.[69-74] This profile differs from that of HRS cells in CHL, which typically show CD20 expression in only a subset of neoplastic cells and cases.[75,76] CD79a is usually positive but varies in intensity.[37] LP cells commonly lack CD19.[77,78] LP cells also stain for CD40, CD70, CD80, CD86, HLA class II, and CD74 (the invariant chain of HLA class II).[79,80] All of these are also expressed in normal GC blasts, with the exception of CD70, which is the receptor for CD27. In normal GCs, CD70 expression appears to be confined to GC blasts expressing only IgD, which can be seen sporadically in clusters in GCs of the tonsil.

Table 26-2

AID, Activation-induced cytidine deaminase; *APC,* antigen presenting cell; *AP1,* activator protein-1; *BAFF-R,* B-cell–activating factor receptor; *CSR,* class-switch recombination; *EMA,* epithelial membrane antigen; *FREB,* Fc receptor homologue expressed in B cells; *GC,* germinal center; *GCET,* germinal-center B-cell–expressed transcript; *HGAL,* human germinal-center–associated lymphoma protein; *IG,* immunoglobulin; *IL,* interleukin; *MHC,* major histocompatibility complex; *NFAT,* nuclear factor of activated T cells; *NF-κB,* nuclear factor-κB; *NTAL,* non–T-cell activation linker; *PCNA,* proliferating cell nuclear antigen; *SHM,* somatic hypermutation; *SWAP70,* switch-associated protein-70; *TF,* transcription factor; *TNF,* tumor necrosis factor; *TOP2A,* topoisomerase II alpha enzyme.

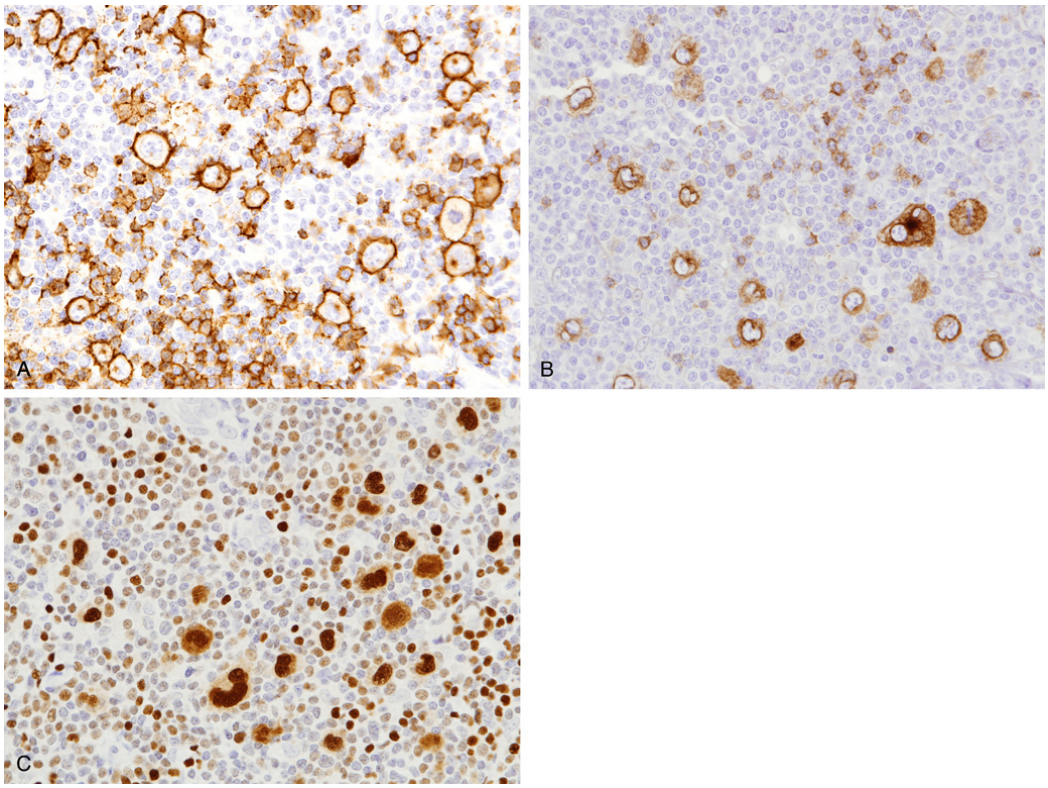

FIGURE 26-6 **A,** Immunostain for CD20 showing membrane staining of several lymphocyte-predominant (LP) cells and background small B-cells. **B,** This case involving a 7-year-old male child was positive for IgD. **C,** OCT2 is strongly positive in the neoplastic cells, a finding that facilitates their recognition.

CD30 staining is usually negative.[81-83] In a few cases, weak, usually cytoplasmic staining of LP cells can be discernible. The NLPBL-derived cell line DEV also expresses CD30, albeit less intensely than CHL-derived cell lines.[84] Thus, expression of CD30 should not totally exclude a diagnosis of NLPHL.[30,63] In contrast, CD30-positive parafollicular immunoblasts located outside the B-cell nodules are commonly identified and represent a potential

diagnostic pitfall.[81] LP cells are typically negative for CD15, but CD15 may be expressed in a subset of neoplastic cells in otherwise typical cases.[30,37,62]

LP cells, in contrast to classical HRS cells, produce J chain, a 15-kD polypeptide essential for linking to the tailpieces of multimeric immunoglobulin molecules.[85-87] LP cells infrequently express demonstrable cytoplasmic IgG, IgM, and IgA. However, strong expression for only IgD is identified in a subset of cases, most often in young males with cervical lymph node involvement (**Fig. 26-6B**).[88] Fc receptor homologue expressed in B cells (FREB), a member of the family of Fc receptors for IgG, is expressed in normal GC B cells, mantle zone cells, and most NLPBLs.[89] Activation-induced cytidine deaminase (AID) is indispensable for class-switch recombination and somatic hypermutation of immunoglobulin genes. In keeping with the notion that LP cells represent transformed GC B cells showing evidence of somatic hypermutation, AID is consistently expressed in LP cells.[90] Other markers of GC derivation, such as GC B-cell expressed transcript 1 (GCET1),[91] human GC-associated lymphoma protein (HGAL),[92] and switch-associated protein-70 (SWAP70),[93] are also expressed in most NLPBLs. CD10 is negative.[94]

Signaling Intermediates

Among transmembrane adapter proteins studied to date, LP cells express only the non–T-cell activation linker (NTAL) that is also expressed in most B cells and B-cell neoplasms.[95] This linker functions as a negative regulator of early stages of B-cell receptor signaling. Syndecans (SDCs) are transmembrane proteoglycans that

play an important role in cell-matrix and cell-cell interactions and in modulating receptor activation.[96] In hematopoietic cells, SDC1 (CD138) is expressed only in B cells at pre-B and plasma cell differentiation stages.[97] LP cells are SDC1 negative, in accordance with their derivation from GC B cells.[94,98]

In most CHL cases, several receptor tyrosine kinases are expressed, whereas none are detected in 50% of NLPHL cases. Receptor tyrosine kinase A, which is essential for the survival of memory B cells, was expressed in only 30% of NLPHLs in one study.[99] JAK2, an intracellular non-receptor tyrosine kinase that transduces cytokine-mediated signals via the JAK2/STAT pathway, is expressed in most NLPHLs.[100]

Transcription Factors and Regulators

B-cell transcription factors such as PAX5, OCT1, OCT2, and BOB.1 are consistently expressed in LP cells (**Fig. 26-6C**).[101] ID2, which is uniformly expressed in the HRS cells of CHL and likely represses B-cell–specific gene expression, is also aberrantly expressed in LP cells and might contribute to the reduced expression of some B-cell genes.[102] PU.1 is variably expressed in NLPBL but absent in both CHL and THRLBCL[103,104] IRF4 (MUM1) cooperates with PU.1 as a transcriptional regulator in lymphoid cells.[105] In LP cells, BCL6 is consistently present, and IRF4 is inconsistently expressed.[94,98] BLIMP1 (PRDM1), a transcriptional repressor that induces plasmacytic differentiation in B cells,[106] is negative in both CHL and NLPBL.[107]

FOXP1 is expressed in normal activated B cells[108,109] and in DLBCL of the activated B-cell type[110] but is absent in both CHL and

NLPBL.[111] T-bet (TBX21) is expressed in Th1 CD4-positive T lymphocytes[112] and a subset of T-cell NHLs, and it may participate in immunoglobulin class switching during B-cell development.[113] In reactive lymphoid tissues, the vast majority of B cells do not express T-bet,[114] whereas the neoplastic cells of NLPHL and CHL are positive.[115] Other T-cell transcription factors such as GATA3, c-MAF, and GATA2 are not expressed in LP cells,[115,116] which is in keeping with the known ability of PU.1 to inhibit expression of GATA transcription factors.[117] Nuclear factor of activated T cells (NFAT) is required for effector differentiation in T cells and normal homeostasis and differentiation in B cells.[118] NFATc1 normally resides in the cytoplasm but relocates to the nucleus when activation of the pathway leads to its dephosphorylation. LP cells show cytoplasmic NFATc1 staining in most cases and nuclear NFATc1 staining in some cases, whereas NFATc1 is expressed in only a minority of CHLs.[119]

Nuclear factor-κB (NF-κB) plays a key role in the regulation of immune and inflammatory responses, functions as a potent inhibitor of apoptosis, and is involved in the malignant transformation of different cell types.[120] The NF-κB family members p50, p52, p65 (RELA), RELB, and REL (c-Rel) form different homodimers or heterodimers in a highly context-dependent manner. Constitutive NF-κB activation promotes proliferation and survival of HRS cells in CHL.[121] REL generally is not expressed in NLPBL,[122] but p65 is expressed in all cases.[123] Most B-cell lymphoproliferative disorders (78%) express B-cell–activating factor receptor (BAFF-R), which is required to activate the alternative NF-κB pathway.[124] NLPBL exhibits weak-to-negative BAFF-R staining,[125] which may imply that

the alternative NF-κB pathway is inactive in LP cells. The activator protein-1 (AP1) family of transcription factors has been implicated in the control of proliferation, apoptosis, and malignant transformation. The AP1 family member JUNB binds to the *TNFRSF8* (CD30) promoter and promotes CD30 expression in classical HRS cells,[126] whereas LP cells are typically weakly positive for JUNB and often negative for CD30.[127,128] LP cells also consistently express myocyte enhancer factor 2B (MEF2B) but lack nuclear staining for STAT6, in contrast to CHL.[30,85,129]

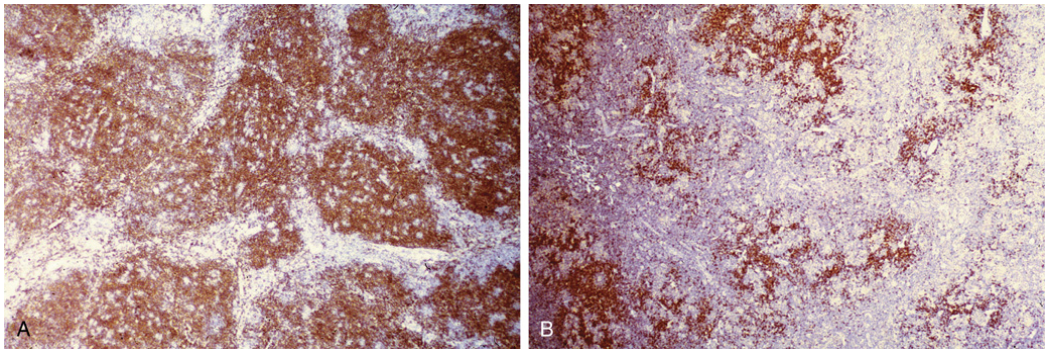

FIGURE 26-7 Immunostains for CD20 show a large majority of positive-staining small B lymphocytes in the nodules of one case of NLPBL **(A)** and a minority of CD20-positive small B cells in another case **(B).**

Cell Cycle Proteins

Immunostains for proliferation-associated nuclear proteins such as Ki-67 or proliferating cell nuclear antigen are positive in LP cells, indicating they are in cycle.[130] The topoisomerase II alpha enzyme (TOP2A), which controls and alters the topologic states of DNA

during transcription and is the target for several chemotherapeutic agents, is highly expressed in LP cells.[131] High TOP2A expression in LP cells might correlate with a favorable outcome in patients with NLPBL treated with TOP2A inhibitors such as doxorubicin or epirubicin.

Tumor Suppressors and Apoptosis-Related Proteins

Caspase 3, which is important for CD95/Fas-mediated apoptosis, is not expressed at detectable levels in NLPBL, similar to low-grade NHL.[132,133] The competitive negative regulator of Fas-induced apoptosis, c-FLIP, is expressed in fewer NLPBLs (32%) than CHLs (81%) or DLBCLs (93%).[134] In contrast to CHL, p53 is not expressed in NLPBL.[135] However, the p53 family member p63, which has both developmental and putative tumor-suppressor functions,[136,137] is expressed in a subset of GC B cells and in NLPBL, but not in CHL.[138] The balance between antiapoptotic BCL2 and proapoptotic BAX is important for the induction of programmed cell death[139]; though BCL2 is not expressed in LP cells,[35] BAX is expressed in all cases.[140] A20 and TRAF1 are two antiapoptotic components of the tumor necrosis factor receptor (TNFR) family signaling pathway induced by CD30 stimulation.[141] A20 (but not TRAF1) is expressed in NLPBL, although it is expressed in variable numbers of LP cells.[122,141] Because most NLPBLs are CD30 negative, stimulation of another TNFR family member, such as CD40, might control A20 expression in LP cells.[142]

Structural Proteins and Adhesion Molecules

Vimentin[143] and fascin,[144] usually positive in classical HRS cells, are not expressed by LP cells. Staining for CD44H shows variable

membranous and Golgi-area reactivity in the neoplastic cells of all CHLs but is negative in NLPBL.[145] Epithelial membrane antigen may be expressed by LP cells[68,146] but is often identified in only a small proportion of neoplastic cells and is negative in many cases, limiting its diagnostic utility.

Background Cells

LP cells usually reside in a background of small B cells, most of which derive from the follicular mantle and express IgM and IgD.[147,148] These lymphocytes also express CD20, CD21, CD22, and CD45RA, but not CD45RB (**Fig. 26-7**; **Table 26-3**).[7,69,71,73,114,148-153] The expression of CD23 is relatively strong, which has also been noted in PTGC. Over time, the proportion of small background B cells tends to decrease, and in multiple-relapse cases, B cells may be few in number.

The number of T cells in the nodules of NLPBL is highly variable, ranging from a minority to a vast majority of cells.[69] In one study, flow-cytometric analysis identified a mean of 61% T cells in five NLPBL cases.[154] The proportion of T cells in the nodules appears to increase over time, and a high proportion of T cells can be found in recurrences. Occasionally, the background T cells may be cytologically atypical, mimicking peripheral T-cell lymphoma (PTCL), but they are nonclonal and retain a normal T-cell phenotype.[155]

A significant proportion of the T cells in NLPBL has a distinctive immunophenotype: c-MAF$^+$, CD2$^+$, CD3$^+$, CD4$^+$, PD1$^+$, CD57$^+$.[69,114,148,151,156,157] Even if few, the T cells usually directly surround the LP cells in rosettes or collarettes (**Fig. 26-8**).[73] CD4-

positive CD57-positive T cells are normally present exclusively in GCs and are mostly confined to the light zones (**Fig. 26-9**).[158] They are not present in the early phases of GC reactions, when proliferating small centroblasts predominate, nor are they in the population of CD4-positive T cells that can be identified in a sharp rim at the border of the GC and mantle zone. These "rim cells" are CD40L positive and are absent in the nodules of NLPBL and PTGCs. CD4-positive CD57-positive T cells in reactive GCs express the chemokine receptor CXCR5, similar to the small B lymphocytes, and are attracted by the chemokine CXCL13 produced by FDCs. CD4-positive CD57-positive T cells themselves also produce high amounts of CXCL13 upon activation, in contrast to extrafollicular T cells,[159] and have a gene expression profile consistent with T-regulatory-1 cells.[154] Data indicate that the rosetting T cells in NLPBL also express CD69 and have TCR proteins that interact directly with class II MHC proteins on the LP cells, suggesting their participation in an immunologic synapse that might represent a therapeutic target.[160] Live cell imaging analyses have demonstrated the dynamic nature of these immunologic synapses.[161]

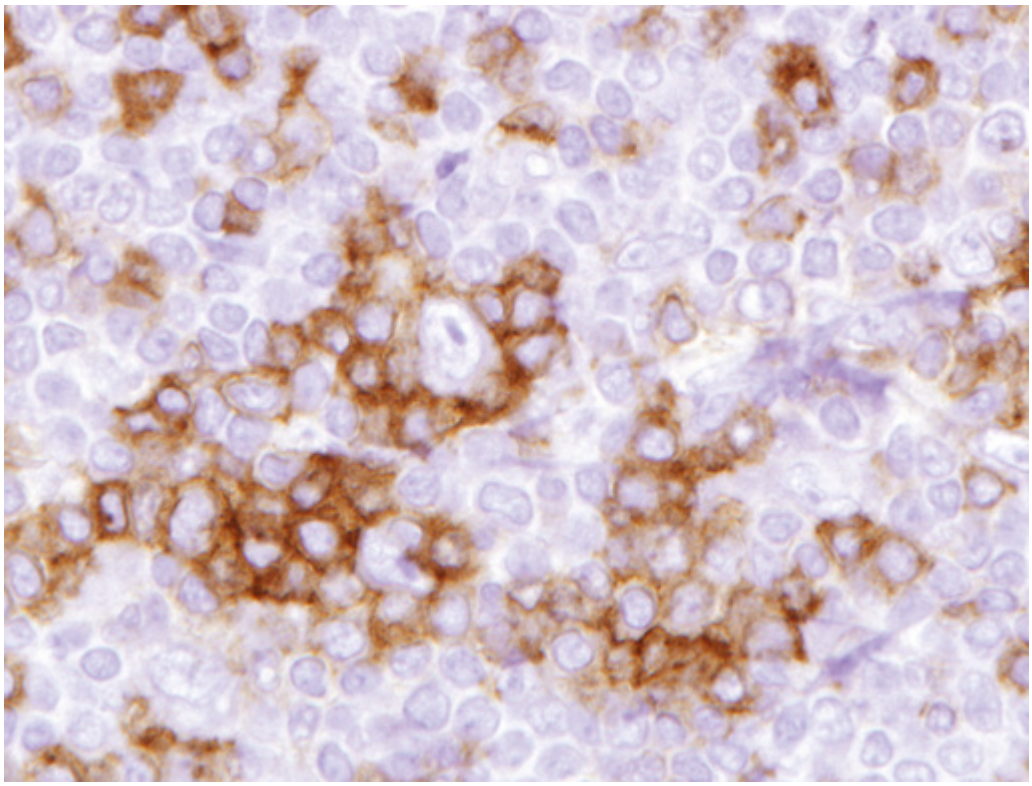

FIGURE 26-8 LP cell surrounded by an almost complete rosette of PD1 (CD279)-positive lymphocytes.

Table 26-3

FDC, Follicular dendritic cell; *GC,* germinal center; *Ig,* immunoglobulin; *IL,* interleukin; *MHC,* major histocompatibility complex; *NK,* natural killer.

Most NLPBLs contain a nonneoplastic mature T-cell population co-expressing CD4 and CD8, constituting 10% to 38% of T cells; these may reflect an activated or reactive T-cell subset and should not lead to a misdiagnosis of PTCL.[162] NLPBLs bearing this population do not differ from other NLPHLs in terms of clinical, histologic, or immunohistochemical features.

The FDCs predominant within the macronodules are CD21 positive and CD35 positive but CD23 negative, thus resembling the FDCs of the mantle zone and not those of the GC (**Fig. 26-10**). They do not carry immunoglobulin complexes. The major interaction between FDCs and B cells appears to be mediated by the CD11a/CD18 (LFA1) and CD54 (ICAM-1) pathway.[163] LP cells also express the adhesion molecules CD50 (ICAM-3) and CD54 (ICAM-1) and thus interact with rosetting T cells.[164] Both FDCs and the rosetting CD57-positive/PD1-positive T cells tend to be lost in pattern E NLPBL.[57]

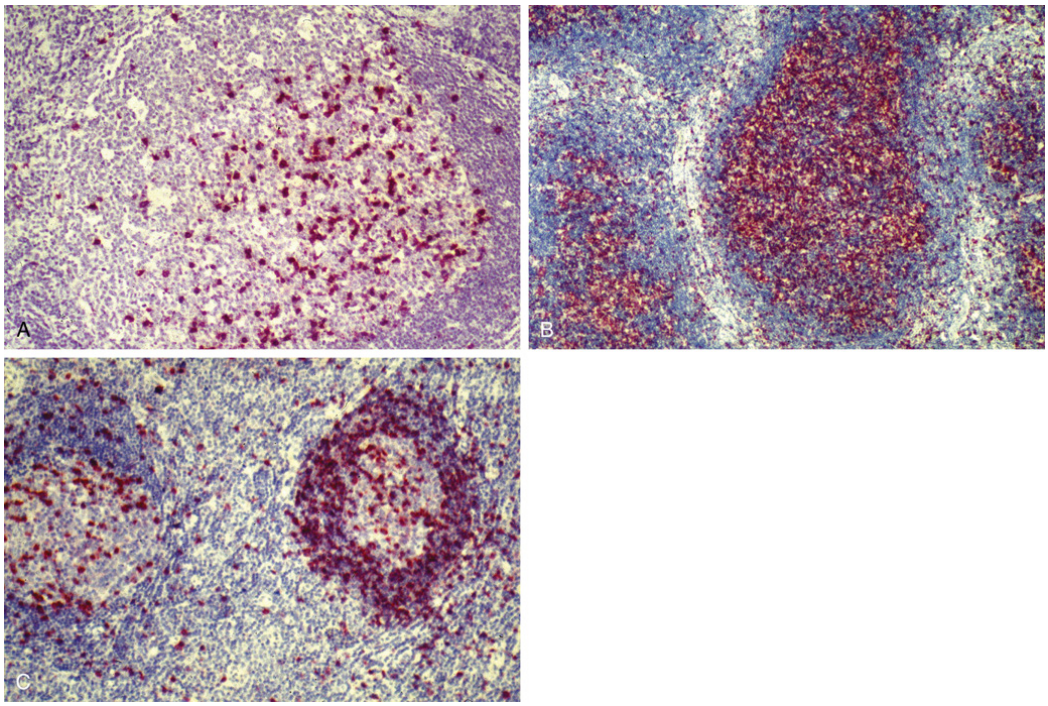

FIGURE 26-9 Immunostains for CD57 show positive lymphocytes in the light zone of a normal secondary follicle **(A)** and an increased number of positive lymphocytes in progressively transformed germinal centers **(B)** and in the mantle zone of a morphologically normal secondary follicle **(C)** in a case of follicular hyperplasia with progressively transformed germinal centers.

Genetics and Molecular Findings

Cytogenetic Findings

Few cytogenetic data on NLPBL are available. All cases studied have a complex karyotype with more than three numerical or structural abnormalities, but most are in the diploid range (46 to 49 chromosomes); tetraploidy, often seen in CHL, is rare.[165,166] With conventional cytogenetics, significant imbalances involve chromosomes 1, 4, 7, 9, and 13.[166] In contrast, comparative genomic hybridization has shown a high number of genomic imbalances (average 10.8 per case) involving all chromosomes except 19, 22, and

Y.[167] Gains of 1, 2q, 3, 4q, 5q, 6, 8q, 11q, 12q, and X and loss of chromosome 17 were identified in 36.8% to 68.4% of the analyzed cases. There was frequent overrepresentation of chromosome arm 6q, a region frequently deleted in DLBCL. Cytogenetic analysis of the NLPBL-derived cell line DEV revealed a 48,XY,+X,t(3;7)(q13;p21),der(3)t(3;14)(p14;q32),t(3;22)(q27;q11.2),+12,der(14)t(3;14)(p14;q32),der(22)t(3;22)(q27;q11.2) karyotype.[76] Array comparative genomic hybridization (aCGH) identified a 3-Mb homozygous deletion was in the 17q24 region,[84,167] though this finding was not confirmed by immunofluorescence for CD20 and fluorescence in situ hybridization (FICTION). An additional aCGH study identified similar copy number abnormalities in NLPBL and THRLBCL, particularly gains of 2p16.1 (including *REL*) and losses of 2p11.2 and 9p11.2.[168]

Recurrent rearrangements of the *BCL6* gene are detected in approximately 50% of NLPBL cases analyzed by interphase fluorescence in situ hybridization[169] and by FICTION.[170,171] *BCL6* aberrations in NLPBL target immunoglobulin and nonimmunoglobulin loci, similar to those found in DLBCL.[170,172] The NLPBL-derived cell line DEV shows a *BCL6* rearrangement with a break in the *BCL6* alternative breakpoint region.[84] FICTION analysis revealed no breaks in the *BCL6* alternative breakpoint region in 12 NLPBL cases, suggesting such breaks may not be common in primary cases of NLPBL.[84] A study demonstrated multiple copies of *BCL6* in the LP cells of some NLPBLs that lack *BCL6* rearrangements.[171] *BCL2* gene rearrangements have been investigated and detected in a small number of cases.[173,174] It is not clear whether the rearrangement was present in LP cells or, more

likely, in bystander B cells. Because LP cells generally do not express BCL2 protein, *BCL2* translocation probably does not play a role in the pathogenesis of NLPBL.

Immunoglobulin and T-Cell Receptor Gene Rearrangement Studies

The relative paucity of LP cells in NLPBL has made clonality studies difficult. Though early studies using in situ hybridization (ISH) to detect Igκ or Igλ messenger RNA yielded variable results,[175-178] ultrasensitive ISH demonstrated light chain restriction in all NLPBLs tested.[179] Southern blot studies were of limited use in showing immunoglobulin gene rearrangement, given their relatively low sensitivity and the rarity of LP cells in involved tissues.[173,180] Polymerase chain reaction (PCR) studies on total tissues also yielded conflicting results.[181-183] These discrepancies result from PCR's limited sensitivity owing to the large numbers of reactive B cells present in NLPBL. The most recent PCR-based studies of multiple microdissected LP cells from individual patients have demonstrated the presence of monoclonal immunoglobulin gene rearrangements.[184-186] The same clone has been shown in multiple nodules, multiple paraffin blocks, and multiple lymph nodes from the same patient. NLPBL exhibited ongoing mutations within clonally rearranged gene segments, with intraclonal diversity in the majority of cases. Ongoing mutations are normally confined to GC B cells. This agrees with the finding that the immunoglobulin gene sequences are translated into functional membrane immunoglobulin expression and are therefore subject to antigen selection.

The T-cell receptor (TCR) V-beta chain gene repertoire of rosetting T cells was studied in two cases of NLPBL.[187] There was no evidence of clonal restriction or selection of V-beta receptor gene expression. Trumper and associates[188] examined rosetting complexes of a single NLPBL case by single-cell analysis for the TCR-γ gene. They found clonal TCR-γ sequences in two independent experiments analyzing 7 and 10 different rosetting complexes. These findings have not yet been confirmed by other studies, although rare cases of PTCL have been seen in patients with NLPBL.[56]

Mutation and Gene-Expression Studies

Similar to DLBCL and CHL, the tumor cells of NLPBL are targeted by aberrant somatic hypermutation in at least one of four proto-oncogenes encoding signal transducers and transcription factors involved in B-cell development, differentiation, and lymphomagenesis (*PIM1, PAX5, RHOH,* and *MYC*).[189] Also similar to CHL, mutations of the suppressor of cytokine signaling *SOCS1,* which is involved in cytokine-induced JAK/STAT activation, are seen in 40% to 50% of NLPBL.[100,190] Unlike CHL, however, mutations and copy number alterations in other genes involved in JAK/STAT activation, including *JAK2, STAT6, PTPN1,* and *CSF2RB,* are rarely observed in NLPBL.[100,190] Other than gains of *REL,* other events implicated in NF-κB activation in CHL, including gains of *MAP3K14* and *BCL3* and mutations in *NFKBIA, NFKBIA,* and *TNFAIP3,* are rare in NLPBL.[190,191] Furthermore, genetic alterations associated with immune evasion in CHL, including those involving *B2M, CIITA, CD274* (PD-L1) and *PDCD1LG2* (PD-L2), are not characteristic of NLPBL.[190] Conversely, in addition to *BCL6* rearrangements,

mutations in *SGK1, JUNB,* and *DUSP2* each occur in about 50% of NLPBL but are not typically seen in CHL.[127,190,192]

Gene-expression profiling of microdissected LP cells has shown similarities to both CHL and THRLBCL, including evidence of constitutive NF-κB activation.[193] The proto-oncogene *BIC* (B-cell integration cluster or pre–miR-155) and mature miR-155, which is now considered an onco–micro-RNA,[194] are highly expressed in NLPHL and CHL.[195,196] LP cells also show expression of the *SGK1* kinase gene, and an SGK1 inhibitor induced apoptosis in NLPBL cell line DEV.[127] Hartmann and colleagues compared the gene-expression signatures of microdissected tumor cells from NLPBL, THRLBCL-like NLPBL, and THRLBCL.[197] It is significant that no striking differences in the gene signatures among these entities were identified. The tumor cells in all three groups expressed several markers, most notably HIGD1A and BAT3, and this was confirmed by immunohistochemistry validation. The authors concluded that NLPBL and THRLBCL may represent a spectrum of the same disease and that differences between the distinct clinical and pathologic presentations may be related to microenvironment and immune status rather than differences in the tumor cells themselves. This hypothesis is supported by gene-expression profiling studies on nonmicrodissected samples, which have found a signature suggesting a tolerogenic host immune response in THRLBCL, including genes encoding interferon-γ, toll-like receptors, CCL8, and indoleamine 2,3-dioxygenase (IDO).[198] In contrast, NLPBL showed a microenvironmental signature more similar to follicular hyperplasia.

Paschold et al. used next-generation sequencing (NGS) of the immunoglobulin heavy chain (IGH) gene to map clonal trajectories of NLPBL evolution and transformation.[199] Transformation was associated with the presence of marked intraclonal diversity, suggesting NGS at diagnosis might help identify cases most at risk of transformation. This diversity also suggests a role for antigenic drive in the events leading to transformation, underscoring the need for further study of the role of B-cell receptor antigens in NLPBL lymphomagenesis.[200]

Relationship With Progressively Transformed Germinal Centers

Follicular hyperplasia with progressively transformed germinal centers (PTGCs) is a benign disorder of unknown pathogenesis. It is diagnosed most often in the second decade of life, with a male predominance. Patients present with an asymptomatic, solitary enlarged lymph node in the cervical region.[201] Histologically, PTGC follicles are much larger than normal follicles and have expanded mantles, which intrude on the GC. The PTGC follicles are scattered in a background of follicular hyperplasia (**Fig. 26-11A**). They share with NLPBL the nodular motif of disrupted GCs with increased numbers of small B lymphocytes and dispersed centroblasts; thus, they may mimic NLPBL both cytologically and by the presence of large numbers of T cells, including CD4-positive CD57-positive cells. However, in PTGC, the T cells are dispersed, whereas in NLPBL, the T cells are in clusters surrounding the LP cells.[68] Prominent FDCs and multinucleated Warthin-Finkeldey–type giant cells can also be seen in PTGC. Immunophenotypic studies of PTGC show polyclonal

IgM-positive, IgD-positive lymphocytes; FDCs; and increased numbers of CD4+, CD57+, c-MAF+, and CD4+/CD8+ T cells.[114,162] A key difference between PTGC and the nodules of NLPBL is the absence of LP cells and the persistence of normal GC cells, including centroblasts (**Fig. 26-11B**).

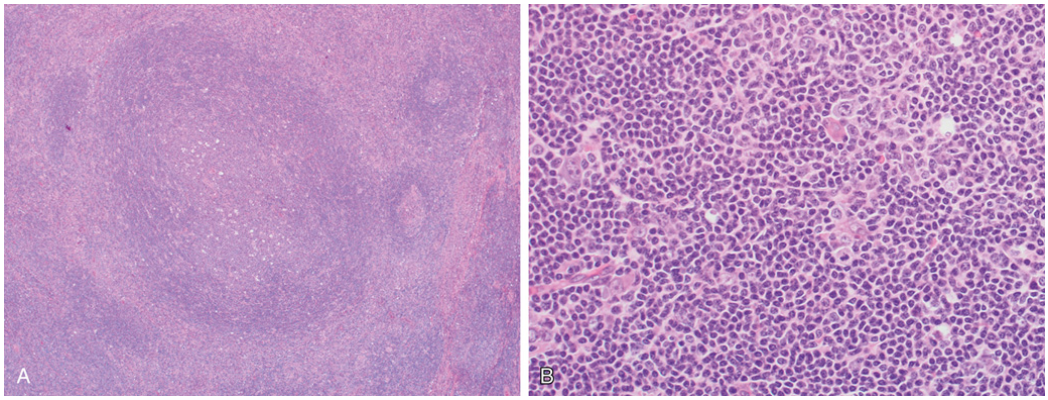

FIGURE 26-11 **A,** Lymph node with follicular hyperplasia and a progressively transformed germinal center. **B,** At higher magnification, a predominance of small lymphocytes and a few centroblasts can be identified.

Early studies suggest an association between PTGC and NLPBL.[7] All possible combinations were encountered, with PTGC preceding or following NLPBL or occurring in separate lymph nodes at the same time. Many other studies have confirmed this association.[202,203] The frequent association and the structural similarity between PTGC and the nodules of NLPBL suggested PTGC is a precursor of NLPBL or, alternatively, that PTGC and NLPBL are manifestations of an abnormal follicular-center reaction based on B-cell or T-cell defects. Patients with concurrent PTGC and different

types of immunodeficiencies have been reported.[204] Of note, no study has convincingly shown that the presence of a few PTGCs in a case of reactive follicular hyperplasia carries an increased risk for development of NLPBL. Moreover, PTGC is not a clonal process.[205] However, confluent areas of PTGCs should raise the index of suspicion and mandate careful sectioning of the entire lymph node biopsy to rule out focal NLPBL. When the absence of LP cells precludes a diagnosis of NLPBL, a high incidence of NLPBL is found in subsequent biopsies.

Differential Diagnosis

PTGC differs histologically from NLPBL in that LP variants are absent. Epithelioid histiocytes are absent in the expanded follicles but may form a necklace-like reaction around them, as sometimes seen in NLPBL. In contrast to NLPBL, in which complete obliteration of the lymph node is generally observed with only a rim of displaced normal tissue, the lymph node is not totally involved in PTGCs. There is virtually always associated florid follicular hyperplasia. A combination of pan-B and pan-T antigens can be a useful adjunct to morphology in distinguishing NLPBL from PTGCs.[68] Immunostains for CD20, BOB.1, and especially OCT2 may be useful in highlighting the LP cells. Stains for CD3, CD57, and PD1 may highlight rosettes around LP cells, which are not seen in PTGCs. PTGCs may be associated with increased polyclonal IgG4-positive plasma cells, a finding not seen in NLPBL.[206]

Association With Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome (ALPS) is generally caused by a mutation in genes associated with apoptosis, such as *FAS, FASL, CASP8,* and *CASP10*. As a result, the normal homeostasis of T and B lymphocytes is disturbed, and proliferation of polyclonal T lymphocytes occurs. The proliferating T cells are positive for TCRαβ or TCRγδ, or both, but they lack both CD4 and CD8 (double-negative T cells). Individuals with germline mutations in the *FAS* gene are at high risk for developing non-Hodgkin (14×) and Hodgkin (51×) lymphomas, particularly NLPBL.[207] NLPBL has been reported in two families with ALPS. Moreover, the reactive lymph nodes of patients with ALPS may show PTGC.[204] The common link may be the CD57-positive T cells that are increased in the nodules of NLPHL and PTGC and that are also the proliferative cell population in ALPS.

Transformation To Diffuse Large B-Cell Lymphoma

Between 3% and 14% of patients with NLPBL develop DLBCL, suggesting an underlying B-cell clone that can further transform to DLBCL, most likely the LP cells (**Fig. 26-12**).[7,47,55,208-211] Nodules with an almost pure population of LP cells can be seen in otherwise classical cases of NLPBL, suggesting an intermediate stage in histologic progression. In other cases, NLPBL can be accompanied

by histologically typical DLBCL at the same anatomic site.[212,213] The DLBCL component can have either a GC-like or non–GC-like B-cell phenotype by standard immunohistochemical classifiers. LP cells and DLBCL cells expressed the same type of immunoglobulin light-chain mRNA,[214] and PCR studies and sequence analysis of IgH CDRIII supported a clonal relationship.[214-216] Both NLPBL and NLPBL-related DLBCL typically lack EBV. Al-Mansour and associates found a transformation rate of 14%, higher than that identified in previous studies.[53] Although the clonal relationship of NLPBL and DLBCL was not assessed, transformation occurred as late as 20 years after NLPBL (median time to transformation, 8 years), indicating the need for prolonged follow-up. Older age, IgD negativity, splenic involvement, variant histologic pattern, involvement of >2 sites, and high intraclonal diversity have all been associated with transformation risk.[47,54,199,208]

The prognosis of DLBCL arising in NLPBL is controversial. The studies reported in the literature have too few cases, limited follow-up, and treatment heterogeneity, precluding a firm conclusion. In the study of Ohno and associates,[216] two cases of NLPBL with associated DLBCL showed aggressive behavior, in contrast to the previously published findings that patients with DLBCL arising from NLPBL had a good prognosis, with overall and event-free survivals similar to those of de novo NLPBL.[55,217] Publications have suggested that DLBCL arising in NLPBL has a prognosis similar to that of de novo DLBCL and should be treated as such.[216,218]

Although progression from NLPBL to DLBCL has been well established, fewer cases with an initial presentation of DLBCL before NLPBL have been reported.[57,219] It is uncertain whether the DLBCL

and NLPBL in these cases are clonally related. These DLBCLs had an indolent course, and subsequent NLPBL developed at the same site, suggesting the two processes may be related. Rare cases of concurrent NLPBL and therapy-unrelated PTCLs have been reported.[56,220] These two diseases are probably not clonally related, but the PTCL may be related to the initiating role of T cells in the disturbed GC reaction of NLPBL.

Relationship With T-Cell/Histiocyte-Rich Large B-Cell Lymphoma

Malignant lymphoma with features of THRLBCL is the most common histologic pattern that develops in the evolution of NLPBL.[219] THRLBCL is characterized by a neoplastic population of large B cells scattered in a reactive background of T lymphocytes and histiocytes.[221] An identical pattern may be seen involving the splenic white pulp in a multifocal pattern. In the WHO and ICC classifications, THRLBCL is a subtype of DLBCL and may represent more than one disease entity (see **Chapter 22**). However, THRLBCL is largely similar to pattern E NLPBL, and NLPBL and THRLBCL may be the two extremes of a single spectrum of disease[197]; alternatively, THRLBCL could represent transformation of NLPBL. It is still unresolved whether primary and secondary THRLBCL can be distinguished. Early studies suggested that THRLBCL with LP-type tumor cells might be related to NLPBL (so-called "paragranuloma-like" THRLBCL) (**Fig. 26-13**).[61,219,222] Moreover, NLPBL and THRLBCL can be seen as composite lymphomas, metachronous lymphomas, or multiple members of the same family.[219] Nevertheless, some THRLBCLs diagnosed after

NLPBL lack LP-type cells. Although several morphologic features of THRLBCL are identical to those of NLPBL, most patients with THRLBCL have clinically advanced disease.[221,222] Single-cell studies revealed ongoing mutations in THRLBCL similar to those in NLPBL.[223] A mutational landscape study by Schuhmacher et al. provided additional support for the relationship between NLPBL and THRLBCL.[192] Specifically, recurrent mutations in *JUNB, DUSP2, SGK1, SOCS1,* and *CREBBP* were most frequent in THRLBCL and NLPBL with variant histology. Mutations in *JUNB, DUSP2, SGK1,* and *SOCS1* tended to occur at aberrant somatic hypermutation hotspots, further proving the role of somatic hypermutation in the pathogenesis of NLPBL and THRLBCL.

The BCL6 protein, which is normally present in GC cells, is frequently expressed in LP cells and also in the tumor cells of THRLBCL. It has been proposed that the distinction between NLPBL

and THRLBCL can be made in difficult cases by demonstrating IGH or IGK clonality.[224] However, because NLPBL can progress to diffuse NLPBL or transform to DLBCL, the distinction between these entities remains imprecise. Both CD79a and BCL2 are more frequently expressed in THRLBCL than in NLPBL.[35,225] The neoplastic cells of THRLBCL are leukocyte-specific phosphoprotein (LSP1) positive and generally PU.1 negative,[61,103,104] with some exceptions[226]; in contrast, LP cells are mostly LSP1 negative with variable PU.1 expression.[104] Although the T-cell rosettes typical of NLPHL are less commonly seen in THRLBCL (**Fig. 26-14**),[114,151] this feature is not a reliable criterion to distinguish the two entities. Likewise, expanded FDC meshworks may be useful in diagnosing NLPBL, but diffuse areas of NLPBL often lack FDC meshworks. It has been suggested that a high TIA-1–positive or granzyme B-positive–to–CD57-positive ratio supports a diagnosis of THRLBCL, and a low ratio supports a diagnosis of NLPBL[61,152]; however, strict criteria for using this ratio have not been defined. Similarly, though early data suggested the presence of PD1-positive T-cell rosettes could distinguish NLPBL from THRLBCL, more recent findings suggest this is not a reliably criterion.[227,228] Of note, though 2-dimensional images did not show significant differences in the T-cell infiltrates, reconstructed 3-dimensional images have demonstrated that the T cells in THRLBCL have increased nuclear volume and increased CD8-positive T cell:tumor cell contacts than those in NLPBL.[229]

The question remains whether NLPBL can transform into THRLBCL. Loss of the nodular growth pattern and of CD57-positive T cells may be epiphenomena, with the significant change being

increased malignant potential of the neoplastic B-cell clone. LP cells might undergo further transformation, or LP cells and the neoplastic cells of THRLBCL might have a common precursor, which undergoes a distinct transforming event. Comparative genomic hybridization after single-cell microdissection has revealed overall similarities between NLPBL and THRLBCL, but with more aberrations in pattern E NLPBL and THRLBCL than in typical NLPBL.[168] Other data, however, has shown significantly fewer genomic imbalances in THRLBCL than in NLPBL.[167,230] Thus, the biological nature of NLPBL that progresses or recurs with features indistinguishable from THRLBCL remains unclear. The preferred nomenclature for this situation remains THRLBCL-like transformation of NLPBL.[231]

Other Differential Diagnoses

Other Non-Hodgkin Lymphoma

NLPBL may be architecturally and cytologically similar the floral type of follicular lymphoma, which also has very large nodules. In low-grade follicular lymphoma, centrocytes are admixed with varying numbers of centroblasts that are CD45 positive and CD20 positive and resemble LP cells in some cases. However, the presence of characteristic LP cells with polylobated nuclei, delicate nuclear membranes, and inconspicuous nucleoli helps distinguish NLPBL from follicular lymphoma. In grade 1 follicular lymphoma, all cells have irregular cleaved nuclear outlines and condensed nuclear chromatin, whereas the nuclei of the background cells in NLPBL are mostly round (but also may include some irregular nuclei). Immunophenotyping shows that the neoplastic cells of follicular

lymphoma are CD10-positive monoclonal B cells, unlike the small B cells in NLPBL.

Occasional NLPBLs may demonstrate a background of cytologically atypical T lymphocytes, raising the differential diagnosis of PTCL, not otherwise specified (NOS).[155] Reported cases have shown younger age and more frequent cervical lymph node involvement than those of NLPBLs lacking this finding. Despite the cytologic atypia, T cells from cases tested did not show aberrant loss of pan–T-cell antigens or molecular evidence of clonality. These cases should be differentiated from true cases of composite NLPHL and PTCL, NOS.[56,220]

Lymphocyte-Rich Classic Hodgkin Lymphoma

LRCHL is the major morphologic mimic of NLPBL.[64] In a study of 426 cases that were morphologically interpreted as NLPBL, 115 (27%) were reclassified as LRCHL.[15,232,233] On H&E stains, the presence of regressed GCs is a characteristic feature of LRCHL, distinct from the expanded macrofollicles of NLPBL. In addition, in LRCHL, the HRS cells are mainly seen in the periphery of the nodules, in the marginal zone, whereas LP cells are usually clustered centrally within the nodules. Patients with NLPBL and those with LRCHL have similar clinical characteristics,[233] except that patients with LRCHL tend to be older.[234] Immunohistochemical stains are essential for the distinction of LRCHL from NLPBL (**Table 26-4**). The most important difference is the phenotype of the tumor cells (**Fig. 26-15**). In LRCHL, these are classical HRS cells, expressing CD30 consistently, CD15 frequently, and EBV-encoded RNA (EBER) in approximately 40% of cases; they express CD20 in only some

cases,[233] and then typically in only a subset of HRS cells. Bhargava and colleagues reported that staining for both fascin and JUNB was highly sensitive and specific for LRCHL and was not seen in NLPBL.[235] PD1-positive T-cell rosettes may be seen surrounding the HRS cells of LRCHL, and they are not specific for NLPBL.[227,228] Of note, clonally related NLPBL and CHL in the same patient has been reported, providing evidence in addition to gene-expression data that these entities may be more closely related than previously thought.[52]

Table 26-4

Treatment

Though the optimal treatment for NLPBL remains controversial, treatment approaches for patients with early-stage disease parallel those for low-grade B-cell NHLs more than those for CHL. Some patients in stage IA remain in complete remission after lymphadenectomy alone, and despite previous concerns,[236] data suggest a watch-and-wait approach can be used for selected patients with NLPBL without significantly affecting outcome.[237] Involved-field radiotherapy is effective and is regarded as standard in stage IA NLPBL, with no significant benefit identified from the addition of chemotherapy.[238,239] Rituximab also has excellent activity in previously untreated and relapsed NLPBL,[240] although rituximab alone is associated with a relapse rate of up to 25% in stage IA disease[238,241] and may select CD20-negative subclones, leading to relapse.[242] Even in the relapsed setting, patients with NLPBL may not require high-dose chemotherapy and transplant.[243] For advanced-stage NLPBL, regimens currently used in B-cell NHL, including R-CVP (rituximab, cyclophosphamide, vincristine, prednisone) or R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone) are reasonable options. Eichenauer et al. have reported that the adverse prognostic effect of variant histology in NLPBL can be diminished using PET-2-guided escalated

BEACOPP (bleomycin, etoposide phosphate, doxorubicin hydrochloride (Adriamycin), cyclophosphamide, vincristine sulfate (Oncovin), procarbazine hydrochloride, and prednisone).[48] ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine), highly effective in CHL, is less effective in advanced-stage NLPBL, and spleen involvement has been associated with development of transformation after ABVD-like regimens.[244] Hodgkin-directed therapies have also been associated with ongoing relapses and treatment-related morbidity and mortality[245]—providing a further rationale to distinguish NLPBL from CHL. In summary, for treatment purposes, NLPBL should be considered closer to B-cell NHL than to CHL.

Prognosis

With pathologic staging and standard treatment, mortality from NLPBL is low; nearly all deaths are cardiac related or due to a secondary tumor.[15,246] The prognosis of NLPBL is related primarily to stage and patient age at diagnosis, and survival ranges from 40% to 99%.[219] Life expectancy of patients with stage I NLPBL is about the same as that of the general population. Patients with splenic involvement (stage IIIS) or with stage IV disease have a poor prognosis with current therapies.

Regula and coworkers[66] compared the clinical course of nodular and diffuse variants in 73 patients. Diffuse cases had few relapses and only two disease-specific deaths. Nodular cases showed significantly more relapses, which occurred independent of stage or treatment and were evenly distributed temporally up to 10 years after initial therapy. Because these cases were diagnosed before the

recognition of LRCHL, the results may reflect inclusion of some CHLs. The THRLBCL-like diffuse pattern (pattern E) described by Fan and coworkers was an independent predictor of recurrent disease[57]; however, this result was limited by a short follow-up period for patients without recurrent disease. Hartmann and colleagues studied 423 NLPBLs and found variant histopathologic patterns to be associated with more advanced disease and higher relapse rate than NLPBL with typical histology.[51,58,247] In addition, histologic patterns C to F have been associated with increased frequency of bone marrow involvement in NLPBL.[49,50] Binkley et al. found that variant histology was associated with both inferior progression-free survival and a significantly higher transformation rate.[54] In a report from the German Hodgkin Study Group, Eichenauer et al. reported that variant histology was associated with both stage IV disease and splenic involvement; of note, the adverse prognostic effect was diminished by PET-2-guided escalated BEACOPP chemotherapy.[48] A prognostic score based on a multivariate model, variant histologic pattern, low serum albumin, and male gender could effectively stratify patients into risk groups that predict progression-free and overall survival. Histologically, the majority of relapsed patients have persistence of NLPBL. It is notable that, despite relatively frequent late relapses, NLPBL still maintains an indolent course. The main risk factor related to poor outcome is advanced stage.

Conclusion

NLPBL is a rare B-cell lymphoma of GC derivation that differs from CHL in histology, immunophenotype, molecular features, and

clinical presentation. Nevertheless, NLPBL and CHL share the key characteristic of a majority of reactive lymphocytes with a minority of transformed lymphoid cells. Although isolated PTGCs may not be a true risk factor for NLPBL, they are associated with NLPBL in many cases. NLPBL transforms relatively frequently to DLBCL; nodules with increased numbers of LP cells may represent a transitional phase. In some cases of NLPBL with co-existent DLBCL, a clonal relationship has been demonstrated by immunoglobulin gene analysis. Clinically, NLPBL has a good prognosis despite frequent relapses, including relapses in distant sites. However, cases that involve the spleen and bone marrow typically have a poor outcome.

Several questions remain unanswered. What is the functional significance of the CD4-positive CD57-positive T cells in the pathogenesis of NLPBL and PTGC? What are the mechanisms of transformation to DLBCL? Is THRLBCL a biologically distinct disease, or does it represent progression of NLPBL? What molecular genetic abnormalities underlie the spectrum from NLPBL to THRLBCL? Long-term studies are needed to answer these questions.

Pearls and Pitfalls

- Evolving clinicopathologic and molecular data suggest NLPBL is related more closely to B-cell NHL than to CHL, reflected in new terminology and grouping within the lymphoma classification.

- The histologic pattern is of clinical importance, and the pattern should be reported as grade 1 (typical histology; Fan patterns A, B, or C) or grade 2 (variant histology; Fan patterns D, E, or F).
- LP cells may show classical HRS cell morphology, and immunohistochemistry is paramount in distinguishing NLPBL from CHL, particularly the lymphocyte-rich subtype.
- Eosinophils, plasma cells, and neutrophils are rarely observed in the background of NLPBL.
- CD20-positive centroblasts must be distinguished from LP cells in the differential diagnosis of PTGC and NLPBL. These centroblasts are not surrounded by CD57-positive rosettes.
- The most useful markers for diagnosis of NLPBL are CD20, OCT2, IgD, CD3, and PD1 (CD279); CD30 and EBV are typically negative.
- The presence of CD4-positive/CD8-positive T cells should not lead to a misdiagnosis of T-cell lymphoma.
- The preferred nomenclature for NLPBL recurring with features resembling THRLBCL is THRLBCL-like transformation of NLPBL.

Definition

Classic Hodgkin lymphoma (CHL) is a clonal, malignant lymphoproliferation originating from germinal-center B cells. In contrast to most other lymphomas, the malignant cells usually represent only a small minority, between 0.1% and 2%, of the total cellular population of involved tissues. A histopathologic diagnosis of CHL is based on the identification of diagnostic Hodgkin and Reed-Sternberg (HRS) cells in an appropriate inflammatory background. Although many cases of CHL can, in principle, be diagnosed or at

least suspected on the basis of morphology alone, current diagnostic criteria include the characteristic immunophenotype of the neoplastic population to separate CHL from morphologic mimics. HRS cells express CD30 and CD15 antigens in the majority of cases, lack the common leukocyte antigen CD45, and show an inconsistent and heterogeneous expression of B-lineage–specific lymphoid markers.

Classification of Classic Hodgkin Lymphoma and Its Evolution

The classification of CHL has remained remarkably constant over the years (**Box 27-1**). Notwithstanding the significant progress in delineating the cell of origin of CHL, the majority of cases are classified much as they were more than 50 years ago, after the development of the Rye classification.[1,2] This underlines the paramount importance of morphology for the correct diagnosis of this neoplasm. The change in terminology from *Hodgkin disease* to *Hodgkin lymphoma* (HL) was first proposed in the Revised European American Lymphoma (REAL) classification[3] and reflected our better understanding of the nature and histogenesis of this lymphoma. The molecular analysis of single isolated HRS cells firmly established the clonality and B-cell origin of CHL and its derivation from germinal-center B cells, which, together with the establishment of Hodgkin cell lines, brought significant insights into the pathogenesis of the disease.[4-9]

Box 27-1 Classifications of Classic Hodgkin Lymphoma

- Nodular sclerosis classic Hodgkin lymphoma
- Mixed cellularity classic Hodgkin lymphoma
- Lymphocyte-rich classic Hodgkin lymphoma
- Lymphocyte-depleted classic Hodgkin lymphoma

Although it has been argued that the dichotomy between HL and non-Hodgkin lymphoma (NHL) is obsolete in the light of our increased understanding of CHL biology, current classifications retain the term “classic Hodgkin lymphoma” for practical reasons and to highlight the distinct biology of the disease.[10]

In diagnostic terms, the last years have led to refinements in the separation of CHL from mediastinal gray-zone lymphoma (MGZL), EBV-positive diffuse large B-cell lymphoma (DLBCL), and EBV-associated lymphoproliferations both in immunocompetent and immunosuppressed individuals. This also led to the recognition that a diagnosis of primary extranodal CHL should be made with utmost caution, as most of these cases would nowadays be considered different entities, including EBV-positive DLBCL, not otherwise specified (NOS); EBV-positive mucocutaneous ulcer; or others. The renaming of nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) to nodular lymphocyte-predominant B-cell lymphoma (NLPBL) in the 2022 International Consensus Classification (ICC) based on its preserved B-cell program emphasizes the separation from CHL.[11] CHL, in contrast, shows an extensive loss of the B-cell transcriptional program in the neoplastic cells, resulting in the loss

or downregulation of most B-cell specific transcription factors and surface antigens, as a defining feature.[9,12,13]

Hodgkin disease.

Epidemiology

Incidence

HL, including NLPHL (now renamed NLPBL), accounts for approximately 15% to 25% of all malignant lymphomas. With current diagnostic criteria, approximately 95% of HLs fall into the CHL category; the remaining cases are NLPBL. The age-adjusted annual incidence rate of CHL in Western countries is approximately 2 to 4 per 100,000 population. In recent decades, a decrease in incidence has been observed among older adults; however, this can be attributed mainly to the misdiagnosis of NHL as CHL in previous years. In contrast, there has been a slight increase of the nodular sclerosis subtype in young adults. The incidence of CHL is higher in affluent, industrialized nations than in developing countries.[14,15]

Age and Sex Distribution

In industrialized countries, CHL shows a bimodal age distribution: the first, higher peak occurs in early adulthood (15 to 35 years), with a second peak in those older than 55 years. CHL is rare in children and is an exceptional occurrence in those younger than 3 years.[16] The overall male-to-female ratio is approximately 1.5:1. Although males predominate in childhood cases and among older adults, the male-to-female ratio is balanced or even slightly reversed in the early

adulthood peak. The distribution of histologic subtypes varies with age. Although the nodular sclerosis subtype predominates in young adults, especially in females, there is a higher percentage of the mixed cellularity subtype in children and older patients. Developing countries show a distinct epidemiologic pattern: the first incidence peak occurs in childhood, with a predominance of the mixed cellularity subtype, and there is no peak in young adulthood.[14,17]

Nodular sclerosis CHL in young adults is associated with a higher socioeconomic status and smaller family size, factors thought to favor a delayed exposure to common childhood viruses.[18,19] Paradoxically, the early adulthood cases show the lowest frequency of Epstein-Barr virus (EBV) positivity, the only infectious agent so far shown to be associated with CHL. EBV is most often identified in CHL in children and older adults and in association with infection with human immunodeficiency virus (HIV).[20-24]

Familial cases of CHL have been reported frequently, and siblings of CHL patients have an increased risk of developing the disease.[19,25] There is a weak but consistent increase in the relative risk of CHL among certain human leukocyte antigen (HLA) types, and association studies have shown that genetic variants associated with CHL are typically in genes regulating the immune system.[26] Interestingly, carriers of HLA-A∗01 and HLA-A∗02, known to be involved in the cytotoxic response to latency proteins of EBV, show an increased versus decreased incidence of EBV-positive CHL, respectively.[27]

Association With Immunodeficiency Disorders

The risk for developing CHL is increased in patients with some types of immunodeficiency. HIV-infected persons have a 6-fold to 20-fold increased risk of developing CHL.[28,29] In the setting of acquired immunodeficiency syndrome (AIDS), CHL shows a predominance of unfavorable histologies (mixed cellularity and lymphocyte depleted) and advanced-stage disease, and it is almost universally associated with EBV.[30-32] Of note, the risk for CHL is increased in patients undergoing highly active antiretroviral therapy, possibly as result of the reconstitution of the immune system necessary for the inflammatory background of CHL, together with a shift to nodular sclerosis subtype.[24,28,33,34]

A significantly increased risk of CHL has been described in recipients of solid organs and allogeneic bone marrow grafts.[35,36] In either setting, CHL occurs late after transplantation, is almost always EBV positive, and is mainly of the mixed cellularity subtype. The clinical presentation and outcome of CHL in allograft recipients is similar to those in nonimmunocompromised patients.

Etiology

The cause of CHL is still an open question, but owing to the unique epidemiologic and clinical features of the disease, an infectious cause has long been suspected. Detection of EBV in the neoplastic cells of a significant proportion of CHLs has confirmed the involvement of an infectious agent. However, as evidenced by EBV-negative cases, EBV is not mandatory for the development of the disease but probably contributes to the pathogenesis in positive cases.[37]

Individuals with a history of infectious mononucleosis have an approximately 3-fold increased risk of developing CHL, and

increased antibody titers or an altered antibody pattern in response to EBV infection has been demonstrated in patients with CHL.[38-40] The detection of clonal EBV in tissues involved by CHL using Southern blot analysis[41] and the subsequent demonstration of EBV nucleic acids in HRS cells by DNA in situ hybridization (ISH) have confirmed the association between CHL and EBV in a significant proportion of cases.[42] EBV-positive CHL shows a strict latency type II pattern of viral gene expression. In addition to EBV-encoded early RNAs (EBERs), short nontranslated RNA molecules that are abundantly expressed in viral latency (approximately 10^6 to 10^7 copies/cell) and EBV latent membrane protein-1 (LMP-1), the neoplastic cells express EBNA1 and LMP-2A and B but lack EBNA2.[37,43-50] Both immunohistochemistry for LMP-1 and nonradioactive ISH for EBERs are reliable methods for the detection of EBV, as they allow localization of EBV to the neoplastic cells, in contrast to in vitro techniques such as polymerase chain reaction (PCR), which may pick up the presence of latently infected B cells, so-called “bystander” cells present in all seropositive individuals.[45] Although EBER ISH is regarded as the most sensitive method, LMP-1 immunohistochemistry, which shows virtually universal expression by HRS cells in positive cases, helps to separate CHL from other EBV-positive lymphoproliferations. Latency in CHL is tightly controlled, and even in immunosuppressed individuals, there is usually no evidence of lytic infection.[51,52] Expression of EBNA-2, indicative of latency type III, is incompatible with a diagnosis of CHL.[53] EBV is clonal in the neoplastic cells of HL, as shown by Southern blot analysis of the terminal repeat region of the EBV genome.[54] This indicates that the infection takes place before clonal

expansion and implicates a direct role for EBV in the transformation process. The EBV genome is present in episomal (nonintegrated) form, and each infected cell contains multiple copies. In EBV-associated HL, tumor cells in multiple involved anatomic sites contain the virus, as do true tumor recurrences.[55-57]

Functional Consequences of Epstein-Barr Virus Infection

LMP-1, which is strongly expressed by the neoplastic cells in HL, is the only viral protein with proven oncogenic properties.[58] LMP-1 induces an array of phenotypic changes in infected cells, including upregulation of activation antigens and antiapoptotic genes and induction of various cytokines; it can also induce an HRS-like phenotype in germinal-center B cells.[59,60] LMP-1 is a constitutively active CD40 receptor homolog and induces a variety of downstream effects, such as constitutive activation of nuclear factor-κB (NF-κB) and JAK/STAT signaling pathways and upregulation of antiapoptotic genes.[37,59] Of note, virtually all cases of CHL with so-called "crippling" immunoglobulin heavy chain (IGH) mutations are EBV positive, emphasizing the importance of EBV-related genes for rescuing CHL precursor cells from apoptosis.[13] However, there is no clear-cut correlation between EBV positivity and tissue expression of genes known to be regulated by LMP-1 in vitro, and the expression profiles of HRS cells are very similar irrespective of EBV status, indicating the main effect of EBV infection on CHL pathogenesis may lie in the early stage of disease development and in the interaction with the immune system.[61,62]

Epstein-Barr Virus Strains and Variants

Two common strains of EBV, types A and B (or 1 and 2), mainly defined by EBNA-2 and EBNA-3, exist in a worldwide distribution. EBV type A transforms lymphocytes more efficiently and is found in the majority of cases of CHL in nonimmunosuppressed patients. Type B is encountered more often in HIV-associated CHL but has also been found in a higher proportion of cases from Latin America, indicating geographic variations in the prevalence of viral strains can influence their distribution in EBV-associated lymphomas.[37,59,63-65]

In addition to these two viral strains, a number of variations of the EBV genome have been described. Among these, deletions in the carboxy-terminal part of the *LMP-1* gene have received the greatest attention. The deletion variant is not associated with any specific histologic or prognostic features; its frequency in EBV-associated CHL reflects its prevalence in healthy carriers from the same geographic region, with the possible exception of higher frequencies of deletion variants in HIV-associated CHL.[65-68] Of note, CHL cases with EBV type B contain the *LMP-1* deletion very frequently, indicating this deletion may be necessary for the transforming capacity of this less virulent strain.[64,65]

Epidemiology of EBV-Associated Classic Hodgkin Lymphoma

The frequency of the association between EBV and CHL in nonimmunosuppressed patients is influenced by histologic subtype, age at presentation, geographic and ethnic origins, and possibly socioeconomic factors.[12,20,22,59,69] Mixed cellularity CHL is EBV positive in approximately 75% of cases, whereas EBV positivity in the nodular sclerosis subtype ranges from 10% to 25%. Reported rates

for both lymphocyte-depleted and lymphocyte-rich CHL (LRCHL) are variable, probably reflecting differences in diagnostic criteria. However, when stringent criteria are used, lymphocyte-depleted CHL is usually EBV positive. Children and older adults are more likely to have EBV-positive CHL, as are males.[20] Developing countries generally show a higher incidence of EBV-associated disease, reaching almost 100% in childhood cases.[22,65] A history of infectious mononucleosis and atypical prediagnosis EBV serology are associated with an increased risk of EBV-positive, but not EBV-negative CHL, further supporting the pathogenetic role of EBV.[27,40,70]

Etiology of EBV-Negative Classic Hodgkin Lymphoma

Based on observations in EBV-positive Burkitt lymphoma cell lines, it has been proposed that the virus might be lost during the malignant progression of CHL once it is no longer required for propagation of the malignant clone. Although some studies reported detection of defective, rearranged EBV in a fraction of CHL negative for EBERs, results from other groups have not provided evidence for this “hit and run” theory.[71-73] Searches for other candidate viruses, such as human herpesvirus 6 or 8, have failed to provide evidence for their involvement in the pathogenesis of CHL.

Clinical Features

Clinically, CHL manifests first in the lymph nodes in >90% of cases, usually as a slowly growing, painless mass. Cervical (75%), axillary, and inguinal nodes are the most frequently involved sites.

Asymptomatic patients are occasionally diagnosed with mediastinal disease detected on a routine chest radiograph. Symptoms related to specific organ involvement, such as superior vena cava syndrome, bone pain, or neurologic symptoms, can occur. Retroperitoneal lymphadenopathy and splenic involvement are frequent, whereas extra-axial lymph nodes (mesenteric, perigastric, epitrochlear, preauricular, popliteal nodes) are rarely involved. CHL seems to spread in an orderly fashion to contiguous lymph nodes.[74] Bone marrow involvement is relatively rare in CHL, occurring in approximately 5% of nonimmunosuppressed patients. Disease manifestations on both sides of the diaphragm and B symptoms indicate a higher risk of bone marrow involvement.[75]

The distribution of disease correlates with histologic subtype. The nodular sclerosis type typically occurs above the diaphragm, most frequently involving the lower cervical, supraclavicular, and mediastinal nodes and contiguous structures. Patients frequently show an enlarged mediastinal silhouette and present with bulky mediastinal disease (greater than one-third of the intrathoracic diameter) in approximately 50% of cases. The spleen and bone marrow are involved in 10% and 3% of cases, respectively.[12,17,76] The mixed cellularity subtype of CHL presents more frequently in stages III and IV and with B symptoms. It occurs more often below or on both sides of the diaphragm; there is splenic involvement in 30% of cases and bone marrow infiltration in 10%. Bulky mediastinal disease is uncommon. Owing to the change in delineation to an independent subtype, relatively few clinical data are available for LRCHL. It has similarities with NLPBL in terms of clinical symptoms and disease distribution. Seventy percent of patients with LRCHL

present with stages I and II, and bulky disease and B symptoms are infrequent.[77-79] Because of its rarity and changes in diagnostic criteria, clinical features of lymphocyte-depleted CHL are not well described. A predominance of elderly patients with higher-stage disease and predominant involvement of abdominal organs and bone marrow has been reported.[80,81] CHL in patients with HIV infection frequently presents as advanced disease and involves unusual sites.[32,82,83] The bone marrow is frequently infiltrated and occasionally represents the primary diagnostic manifestation of the disease.[82,84]

Approximately 30% to 40% of patients with CHL present with B symptoms. Although B symptoms are more frequent in advanced stages of disease, they can also occur in early stages, possibly as a result of inflammatory cytokines produced by the tumor. The so-called “cyclic Pel-Ebstein” type of fever is rare. Other symptoms include generalized pruritus and occasionally pain in involved nodes upon alcohol ingestion.

Laboratory Findings

Laboratory findings are mostly non-specific and include leukocytosis, elevated erythrocyte sedimentation rate, and increased lactate dehydrogenase. Eosinophilia can be observed in approximately 20% of patients, and lymphopenia is present in advanced disease stages. However, most patients with CHL exhibit demonstrable defects in cell-mediated immunity, regardless of stage.[12] A decrease in CD4-positive cells in the peripheral blood is already detectable at an early stage. T lymphocytes from patients with HL show a weaker response to T-cell mitogens and a decrease in

cytokine production upon stimulation. Clinically, this anergy can manifest as an increased susceptibility to infections and a lack of reactivity in the tuberculin skin test. It is still unclear whether these immune abnormalities are preexistent; they may contribute to disease development or may be secondary phenomena, possibly caused by immunosuppressive cytokines secreted by the neoplastic population.[85,86]

Extranodal Manifestations

Although CHL is almost always a node-based lymphoma, practically any site and organ of the body can be involved during the course of the disease. Although the spleen, bone marrow, and liver are frequently involved in advanced disease, isolated involvement of these organs is rare. Thymic involvement is frequent in mediastinal disease.[87] Rarely, if lymph node involvement is not apparent, CHL can radiologically simulate other neoplasms of the thymus, prompting surgical removal of the thymic mass.[88] The affected thymus frequently shows cystic degeneration. Bona fide CHL is rare in mucosa-associated lymphoid tissue but can occur in the tonsils and Waldeyer's ring.[89,90] Apart from the liver, the lung is probably the most frequently involved nonlymphoid organ, usually as an extension of mediastinal disease. Interestingly, primary CHL of the gastrointestinal tract was initially reported in association with a history of inflammatory bowel disease or immunosuppression.[91] These cases would today probably be classified as EBV-associated lymphoproliferation with Hodgkin-like features, specifically as EBV-associated mucocutaneous ulcer.[92,93] Many other extranodal primary sites of CHL have been reported, mainly in anecdotal form

in older literature. In the skin, CHL may be suspected as a result of the morphologic and phenotypic overlap with CD30-positive lymphoproliferative disorders (LPDs) of the skin, including cutaneous anaplastic large cell lymphoma (ALCL) and lymphomatoid papulosis. Cases of apparently primary cutaneous CHL need to be evaluated with extended phenotyping.[94,95] Central nervous system involvement with CHL is very rare but may exceptionally occur as primary disease.[96] In summary, any diagnosis of primary extranodal CHL, especially in patients without concurrent nodal or systemic disease, should be made with utmost caution and requires extended immunohistochemical studies to rule out morphologic mimics, including EBV-associated LPDs.

Staging

Staging of CHL is performed according to the Ann Arbor staging classification, as last modified in the Lugano meeting.[97] It provides important prognostic information and forms the basis for certain therapeutic decisions. The accuracy of staging in CHL relies on the fact that HL disseminates in a highly predictable manner through lymphatic channels, involving contiguous lymph node stations and other organs in a stepwise fashion.[74,98]

In addition to a detailed clinical history, physical examination, and laboratory studies, staging of HL requires detailed imaging studies, including chest x-ray and contrast-enhanced computed tomography (CT)-scan. Fluorodeoxyglucose positron emission tomography (FDG-PET) in combination with CT (PET/CT) offers greater sensitivity and a higher specificity and is the method of choice for initial staging and during follow-up.[97,99,100] Trephine bone marrow biopsy is not

indicated in asymptomatic early-stage and PET/CT-negative cases owing to the very low rate of bone marrow involvement in these groups.[101,102]

Morphology

Reed-Sternberg Cells and Variants

The diagnostic cell of CHL is the *Reed-Sternberg* (RS) cell. The classic RS cell is large (up to 100 μm) and contains two to multiple nuclei or a large lobated nucleus, rendering the impression of multinucleation on sectioning. The nuclei show an accentuated membrane, pale chromatin, and a single large, eosinophilic, viral-inclusion–like nucleolus (**Fig. 27-1A, C, and D**). The cytoplasm is ample and amphophilic. They can also be identified in cytology specimens, e.g., fine needle aspirates (**Fig. 27-2E**). Mononuclear variants are called *Hodgkin cells* (**Fig. 27-1F**). They can usually be distinguished from immunoblasts by virtue of their larger size; their huge, eosinophilic nucleolus, frequently surrounded by a clear halo; and their more eosinophilic cytoplasm. In many instances, the classic diagnostic RS cells make up only a minority of the neoplastic population, and mononuclear cells and other variants predominate. Frequently, degenerated HRS cells with condensed, darkly stained cytoplasm and condensed nuclear chromatin can be observed—so-called "mummified" cells (**Fig. 27-1E**). However, HRS-like cells and variants can be identified in a range of different disorders and are therefore not sufficient for a diagnosis of CHL.[103,104]

The typical cell of the nodular sclerosis subtype is the lacunar variant of the HRS cell. Lacunar cells show abundant clear to slightly eosinophilic cytoplasm and sharply defined, round cellular borders.

The nuclei are frequently more lobated, with coarse chromatin. The nucleoli are smaller than those in classic HRS cells. Owing to a shrinkage artifact, the cytoplasm is frequently condensed in the perinuclear area, with spider-web–like extensions to the cell membrane leaving lacuna-like spaces, characteristic of this cell type (**Fig. 27-1B**). The lymphocyte-predominant (LP; formerly L&H) variant of the RS cell (or "popcorn" cell) is the characteristic cell type of NLPBL, although morphologic mimics can be seen in LRCHL.[77]

Histologic Subtypes

Based on the morphology of the neoplastic cells, the tissue architecture, and the characteristics of the reactive infiltrate, four subtypes of CHL are currently recognized (**Table 27-1**).[11,105] Although the two most common subtypes, nodular sclerosis and mixed cellularity, are well defined and usually easily recognizable, the two other subtypes, lymphocyte-rich and the rare lymphocyte-depleted, frequently require more extensive immunohistochemical confirmation.

Based on novel insights into disease epidemiology, biology, and genetics, it is currently thought that nodular sclerosis CHL represents a disease entity distinct from the other subtypes of CHL, with a close relationship to MGZL and primary mediastinal large B-cell lymphoma (PMBL).[12,106]

Nodular Sclerosis Classic Hodgkin Lymphoma

This is the most frequent subtype of CHL, accounting for 60% to 80% of cases in most series from Western countries.[12,17,78] Macroscopically, a diagnosis of nodular sclerosis CHL can be suspected in typical cases with advanced fibrosis. The node is firm,

and the cut surface reveals distinct white or yellowish nodules separated by bands of connective tissue. Microscopically, the diagnosis can be suspected at low power because of the presence of cellular nodules surrounded by concentrically arranged collagen bands that show birefringence in polarized light (**Fig. 27-2A**). The nodules frequently show an irregular, mottled appearance resulting from the presence of numerous lacunar cells and may contain areas of frank necrosis and abscess formation (**Fig. 27-2B**).

The presence of fibrosis is a defining feature of nodular sclerosis, but the amount can be quite variable. A discrete thickening of the lymph node capsule and perivascular adventitial structures may be the only clear sign of increased collagen synthesis. At the other extreme, nodular sclerosis can show almost complete obliterative fibrosis of the node, with a paucity of both tumor cells and reactive inflammatory cells. These cases can present significant diagnostic difficulties, especially when only small biopsy specimens are available, such as cutting needle biopsies of mediastinal masses, which frequently show crush artifacts because of the high fiber content. (**Fig. 27-2F-H**)

On high power, lacunar cells are easily recognized (**Fig. 27-2B**). They can be sprinkled throughout the cellular nodules or occur in clusters or compact sheets of cells; the latter is especially true of grade II nodular sclerosis. Classic RS cells are less frequent in nodular sclerosis and may be difficult to identify.

The cellular composition of the reactive background can vary from case to case and from nodule to nodule. Some cases show a predominance of small lymphocytes; more often, a mixed population of lymphocytes, neutrophils, frequent eosinophils, plasma cells, and

macrophages can be found. Fibroblasts are especially frequent in the fibrotic pattern of the disease. Eosinophilic or neutrophilic abscesses are common. Sheets of neoplastic cells and histiocytes often rim foci of necrosis, sometimes raising the possibility of a necrotizing granulomatous process.

Owing to its extreme morphologic variability, subclassification of nodular sclerosis CHL into grades I and II based on histologic features had been proposed for prognostic purposes according to the British National Lymphoma Investigation (BNLI). Nodular sclerosis CHL is classified as grade II if (1) more than 25% of the nodules show pleomorphic or reticular lymphocyte depletion, (2) more than 80% of the nodules show the fibrohistiocytic variant of lymphocyte depletion, or (3) more than 25% of the nodules show numerous bizarre, anaplastic-appearing RS cells. If these criteria are followed, approximately 15% to 25% of cases are classified as grade II.[107-109] This subtyping has lost importance because of improved therapies, which tend to abolish these previously observed prognostic differences.[110] Nodular sclerosis cases with high numbers of tumor cells should be separated from lymphocyte-depleted CHL. By convention, any nodularity of the infiltrate will put a case into the nodular sclerosis category.[111,112] In some cases of CHL with typical lacunar cells, fibrosis is minimal or absent, and there is a prominent nodular pattern with a predominance of lymphocytes. These cases have been designated the cellular phase of nodular sclerosis. Nowadays, some of these cases fall into the lymphocyte-rich category of CHL.[113] A fibroblastic variant of nodular sclerosis with diagnostic importance was observed in the BNLI studies. It is characterized by a diffuse proliferation of fibroblasts, without the heavy collagen

deposition characteristic of conventional nodular sclerosis.[109] These cases can be misclassified as mesenchymal tumor, such as malignant fibrous histiocytoma.

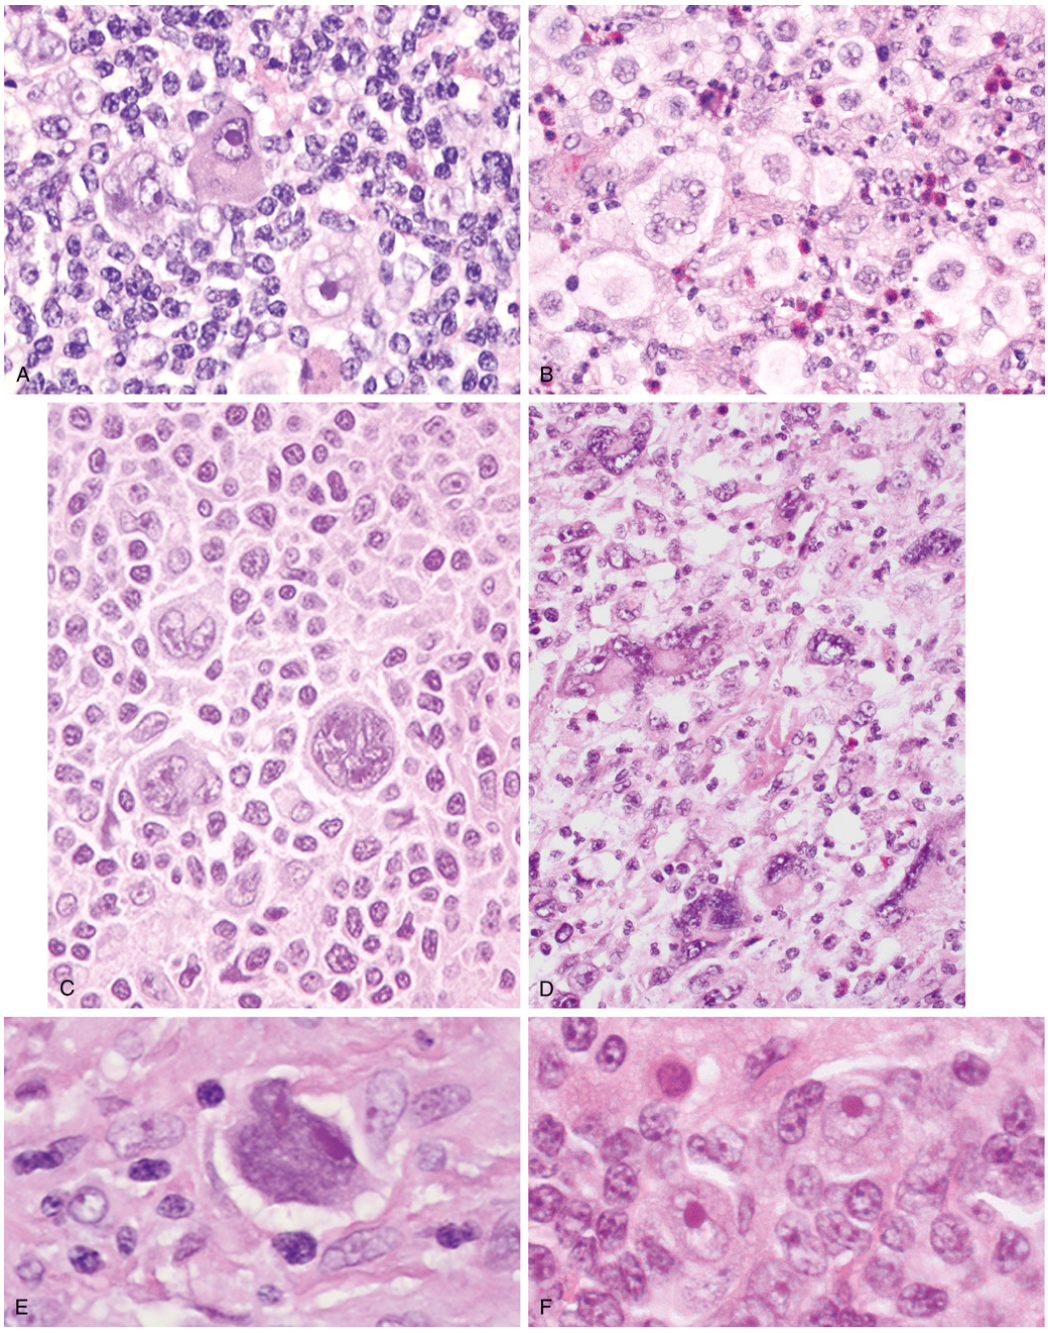

FIGURE 27-1 Cytologic features of Reed-Sternberg (RS) cells and Hodgkin cells.**A,** Classic RS cells and variants in mixed cellularity classic Hodgkin lymphoma (CHL) with amphophilic cytoplasm, large nuclei with clear karyoplasm, and huge, viral inclusion-like nucleoli. **B,** Typical

lacunar cells in a case of nodular sclerosis CHL. Note the delicate, folded nuclear membranes; less conspicuous nucleoli; and ample, clear cytoplasm with thread-like protrusions. **C,** Typical RS cells, including a binuclear variant, in mixed cellularity CHL. **D,** Abundant, sometimes bizarre multinucleated tumor cells in a case of nodular sclerosis grade II. **E,** So-called “mummified” RS cell with condensed, deeply basophilic cytoplasm. **F,** Two classic mononuclear Hodgkin cells in a case of mixed cellularity CHL.

FIGURE 27-2 Morphology of classic Hodgkin lymphoma (CHL).**A,** Nodular sclerosis CHL (NSCHL). Cellular nodules are separated by concentric bands of mature collagen. **B,** Close-up of cellular nodule shows numerous lacunar cells with clear cytoplasm intermingled with lymphocytes, neutrophils, and eosinophils. Note collagen bands rimming the nodule. **C,** NSCHL grade II. Confluent sheets of neoplastic cells with partly anaplastic features, intermingled with a minority of inflammatory cells. This morphology is consistent with the so-called "syncytial" variant of CHL. **D,** Lymphocyte-depleted CHL, diffuse fibrosis subtype. Neoplastic Hodgkin and Reed-Sternberg (HRS) cells in a hypocellular background with histiocytes and fibroblasts. This case lacks nodularity and ordered collagen bands. **E,** Fine needle aspirate of a mediastinal lymph node with CHL. Two large, atypical cells with large nuclei and prominent nucleoli are accompanied by eosinophils and lymphocytes. **F,** Mediastinal core needle biopsy of NSCHL with significant fibrosis and occasional large mononuclear cells. Immunostaining for CD30 **(G)** and CD15 **(H)** highlights the neoplastic HRS cells.

Table 27-1

LP, Lymphocyte predominant; *RS,* Reed-Sternberg.

Cases described as syncytial variant of nodular sclerosis show sheets of neoplastic cells frequently associated with areas of necrosis and increased pleomorphism of the neoplastic cells (**Fig. 27-2C**).[114,115] The main importance of this variant is the potential for misdiagnosis as ALCL or nonlymphoid neoplasm.

Mixed Cellularity Classic Hodgkin Lymphoma

This is the second most frequent subtype of CHL, accounting for 20% to 30% of cases in Western countries. The lymph node architecture is usually diffusely obliterated, although early involvement may show an interfollicular growth pattern or residual, sometimes atrophic germinal centers. Classic HRS cells are frequent, easily identifiable, and usually evenly dispersed throughout the node (**Fig. 27-3A**). The presence of clusters of lacunar cells should raise the possibility of the cellular phase of nodular sclerosis. The background infiltrate consists of a heterogeneous population of small lymphocytes, eosinophils, plasma cells, and histiocytes. The lymphocytes may show some nuclear pleomorphism, but frank background atypia should immediately raise the differential diagnosis of NHL, especially peripheral T-cell lymphoma. In some cases, sometimes termed the *histiocyte-rich variant of mixed cellularity CHL,* clusters of epithelioid histiocytes are present in abundance (**Fig. 27-3B**). These cases need to be separated from various subtypes of histiocyte-rich NHL. Rare cases of CHL show an excessive, sometimes granulomatous proliferation of histiocytes, which can obscure both lymphocytes and the neoplastic cells.[116,117] These cases may

resemble histiocyte storage disorders or inflammatory conditions and require immunohistochemical stains for identification of the neoplastic cells. Phenomena that should not be confused with infiltration by histiocyte-rich mixed cellularity CHL is the presence of noncaseating, sarcoid-type granulomas in lymph nodes or other tissues in the vicinity of involved nodes or abundant histiocytes in nodes excised after treatment for CHL. Although appropriate stains may show a diffuse increase in reticulin fibers, the presence of collagen fibrosis precludes a diagnosis of mixed cellularity CHL. Similarly, necrosis is not a feature of this subtype.

Although mixed cellularity CHL as initially defined in the Rye classification incorporated all cases that could not be included in any other categories, it is now regarded as a true entity, and cases that cannot be classified properly owing to unusual histologic features or limited material should be termed *CHL, unclassifiable*.[111]

Lymphocyte-Rich Classic Hodgkin Lymphoma

This rare subtype of CHL is characterized by the presence of a small minority of HRS cells of the classic type in a background dominated by small lymphocytes.[77,111,113,118,119] Most cases show prominent nodularity, and a diffuse pattern is rare.[77]

Typical LRCHL shows partially preserved lymph node architecture with an easily discernible nodularity. The nodules consist of small B cells and often contain a regressed, eccentrically placed germinal center, sometimes reminiscent of Castleman disease (**Fig. 27-4A** and B). Progressively transformed germinal centers are not a feature of LRCHL. Groups of epithelioid cells, sometimes in a concentric arrangement, can occur, closely simulating the appearance of

NLPBL. Other inflammatory cells, such as eosinophils, are usually rare. The neoplastic cells are present in the expanded mantle zones in a dispersed pattern, and groups or clusters of tumor cells are infrequent. The peculiar location of the neoplastic cells in the mantles of B-cell follicles led to the initial description of this variant as *follicular Hodgkin disease*.[120,121] Classic HRS cells occur in the majority of cases but may be rare (**Fig. 27-4E**). Of note, cells with the cytologic features of LP cells typical for NLPBL, with folded or lobated nuclei and less prominent nucleoli, occur also in LRCHL (**Fig. 27-4C and D**).[77] Therefore, the immunophenotype of neoplastic cells with expression of CD30 and CD15 is crucial for the distinction from NLPBL (**Fig. 27-4F**).[77,112,113,119] The reactive background consists of small immunoglobulin (Ig)M-positive and IgD-positive B cells, typical for the mantle zone (**Fig. 27-4B**). Appropriate stains reveal a fine, expanded meshwork of follicular dendritic cells and highlight the nodular architecture of the infiltrate. The neoplastic cells are frequently rimmed by CD3-positive T cells that may show CD57 and/or PD-1 (CD279) expression, markers of follicular T-helper cells.[77,104,112,113,119]

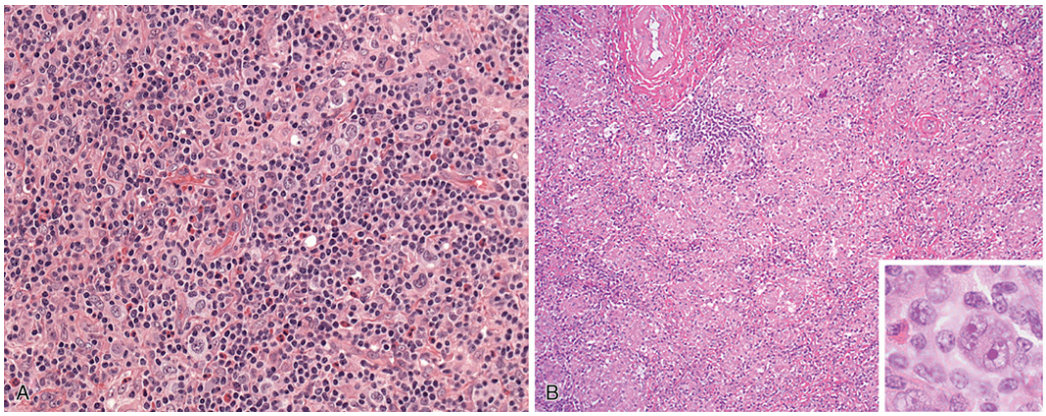

FIGURE 27-3 Mixed cellularity classic Hodgkin lymphoma (CHL).**A,** The lymph node contains a mixed population of lymphocytes, plasma cells, eosinophils, histiocytes, and easily recognizable Reed-Sternberg (RS) cells and variants. **B,** Histiocyte-rich mixed cellularity CHL containing confluent sheets of epithelioid cell granulomas with rare, interspersed RS cells *(inset)*. If areas of more typical mixed cellularity CHL are missing, non-Hodgkin lymphoma with epithelioid cell granulomas (e.g., so-called "Lennert" lymphoma) or even reactive conditions may be considered.

The second, rare variant of LRCHL shows an interfollicular or diffuse growth pattern with classic RS cells in a background of small lymphocytes that, in contrast to those in the nodular pattern, are predominantly of a T-cell phenotype. B-cell follicles are either pushed aside or, rarely, absent.

Overall, LRCHL shows some clinical, morphologic, and immunophenotypical features overlapping those of NLPBL, with

more frequent expression of B-cell transcription factors and a follicular T-cell environment, supporting its place as a specific subtype of CHL, although this has been challenged by some authors.[118]

Lymphocyte-Depleted Classic Hodgkin Lymphoma

This is the least frequently diagnosed subtype of CHL, constituting about 1% of patients in recent series.[81] Many cases from earlier series probably represented aggressive NHL or would today be classified as nodular sclerosis CHL grade II.[122] Two types of lymphocyte depletion can be recognized: diffuse fibrosis and reticular variants. The diffuse fibrosis type shows a hypocellular infiltrate with disordered, diffuse reticulin fibrosis and atypical cells, including HRS cells and a sparse, heterogeneous background population (**Fig. 27-2D**). The presence of organized collagen bands mandates a diagnosis of nodular sclerosis CHL. The reticular variant is characterized by sheets of atypical cells, including many bizarre, anaplastic RS cells. Immunohistochemical demonstration of a characteristic CHL phenotype is required for the exclusion of large cell lymphomas, especially ALCL.[104,112,123,124]

Classic Hodgkin Lymphoma, Unclassified, and Unusual Morphologic Patterns

All cases that cannot be confidently placed in any of the four categories described should be designated CHL, unclassified. Small biopsy specimens or biopsies from extranodal sites, partial lymph node involvement, unusual histologic features, or poor technical quality may preclude subtyping. Partial involvement by CHL is frequently found, especially if a smaller node from the periphery of a

lymph node conglomerate is removed. The infiltrate usually resides in the interfollicular area in a background of T cells, with preserved or regressed germinal centers. This interfollicular pattern may fall into the LRCHL category. RS cells of CHL may occur in monocytoid B-cell clusters, and an accompanying monocytoid B-cell reaction can be observed in a small minority of cases.[125-127] Rarely, sinusoidal involvement by HRS cells and variants can mimic ALCL.

Relapsed CHL usually retains the initial histologic subtype but may show morphologic progression, especially at previously treated sites, with an increase in the number and pleomorphism of tumor cells.[76] These cases are sometimes designated the lymphocyte-depleted subtype, but assignment of the histologic subtype should be based on initial pretherapy biopsies. In patients with suspected relapses of CHL, the possibility of a secondary neoplasm should always be considered if the morphologic and phenotypic criteria for a diagnosis of CHL are not met. Similarly, persistent mass lesions after treatment for CHL may occasionally prompt a biopsy, especially if there is residual PET-positivity.[128] Frequently, only hyalinized scar tissue or histiocyte accumulations can be identified. A diagnosis of residual CHL should be made only if HRS cells can be identified unequivocally by morphology and immunophenotype.

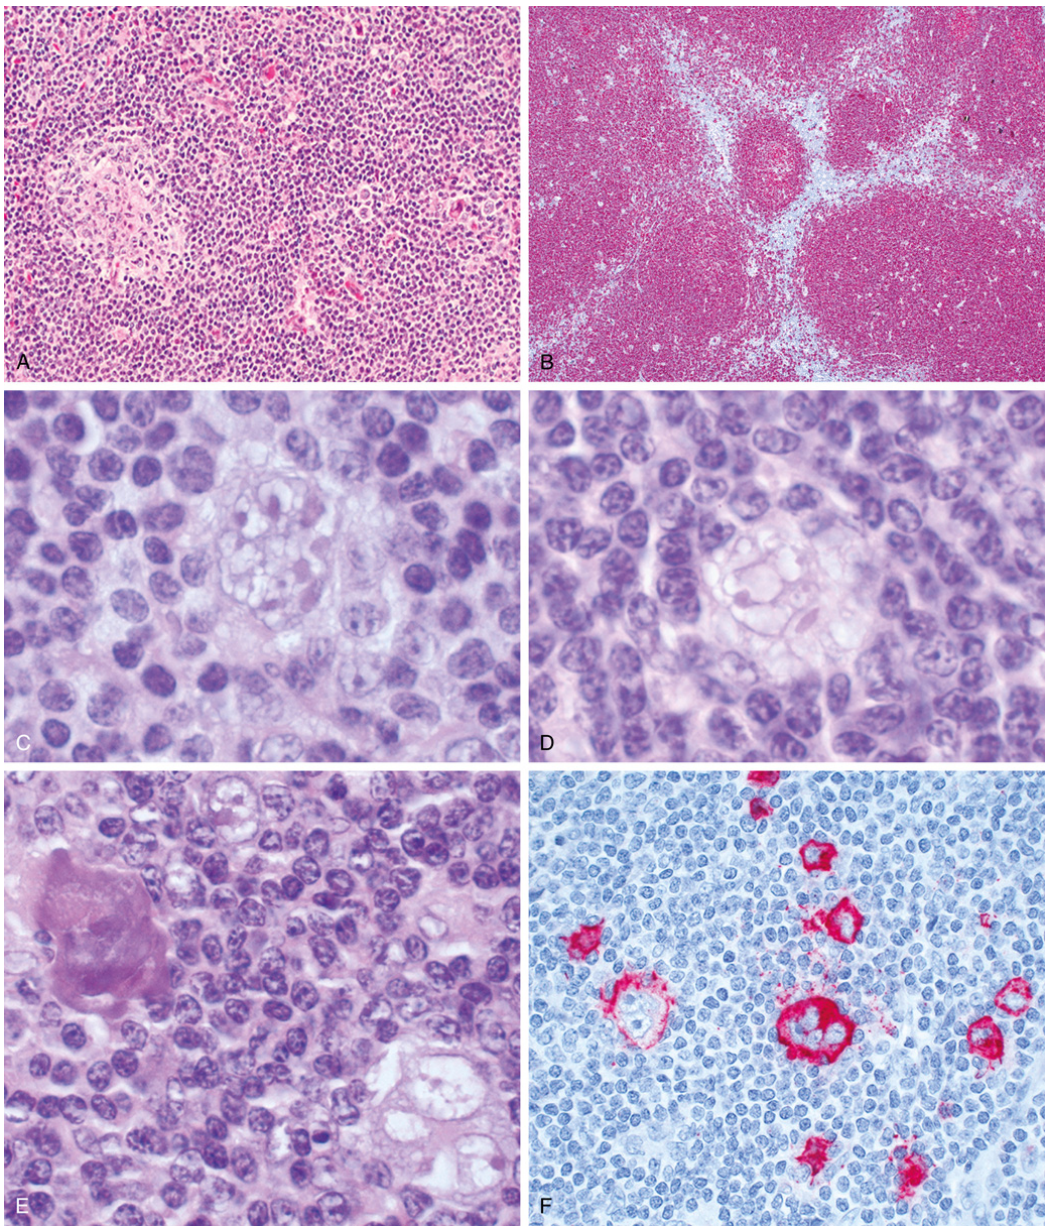

FIGURE 27-4 Lymphocyte-rich classic Hodgkin lymphoma (CHL), nodular variant.**A,** The lymph node is dominated by small lymphocytes arranged in a nodular pattern, frequently with atrophic germinal centers. The tumor cells are found in the expanded mantle zones of these B-cell nodules. **B,** Immunohistochemistry for CD20 highlights the

nodular pattern with a predominance of B cells. **C** to **E,** the morphologic spectrum of neoplastic cells in lymphocyte-rich CHL varies from classic Reed-Sternberg (RS) cells **(E)** to cells resembling the LP cells of nodular lymphocyte-predominant B-cell lymphoma (**C** and **D**). **F,** Immunohistochemistry for CD15 reveals strong positivity of the neoplastic cells, including a classic binucleate RS cell.

Diagnostic Criteria for Extranodal Sites

The criteria for a diagnosis of CHL in an extranodal organ strongly depend on whether the patient has an established diagnosis of CHL at a nodal site. In liver and bone marrow biopsies obtained for staging purposes in patients with CHL, identification of a mixed cellular infiltrate with occasional atypical mononuclear cells with appropriate phenotype is regarded as sufficient for a diagnosis of involvement by CHL, because diagnostic RS cells are lacking in most small tumor foci. In the liver, the infiltrate usually involves the portal triads. In the bone marrow, focal fibrosis detected by reticulin stains is an ominous sign and should prompt further examinations such as step sectioning and immunohistochemistry.[84,129]

As mentioned earlier, the thymus is frequently involved in mediastinal disease, which is almost always of the nodular sclerosis subtype. Thymic CHL can be associated with a prominent reactive proliferation of thymic epithelium intermingled with neoplastic cells and the development of epithelial cysts, sometimes leading to a misdiagnosis of thymoma or multilocular inflammatory thymic cyst

unless generous sampling of the lesion and appropriate immunohistochemical studies are performed.[88]

In contrast to patients with known CHL as described in this chapter, a *primary* diagnosis of CHL in an extranodal site should be performed with utmost caution; most cases from previous series nowadays would be classified as B-cell lymphomas or EBV-associated lymphoproliferations.

Immunophenotype

Owing to the unique features of CHL, both the phenotype of the neoplastic cells and the antigenic profile of the reactive background population are of diagnostic importance. Despite the significant morphologic variability among the four subtypes of CHL, the immunophenotype of the neoplastic cells is quite constant, and minimal sets of markers have been proposed, including CD3, CD20, CD30, CD15, and PAX5, usually complemented by MUM1/IRF4 and detection of EBV by EBER ISH or LMP1 immunostaining.[11,130] The most important antigens of diagnostic relevance are summarized in **Table 27-2**. HRS cells express various activation-associated antigens, including CD30,[131,132] CD25 (interleukin [IL]-2 receptor α chain),[133] CD40,[134] CD71 (transferrin receptor), CD80, HLA-DR, and antigens normally found on such diverse cell types as T-lymphocytes, granulocytes, and follicular dendritic cells.[12,112,135-137] They characteristically lack the common leukocyte antigen CD45 and show inconstant and heterogeneous expression of some B-cell or, rarely, T-cell markers.[138,139] The immunophenotype of CHL may be difficult to assess owing to the immersion of the neoplastic RS cells in an abundant reactive infiltrate, especially for markers expressed

by most or all nonneoplastic cells in the immediate vicinity, such as CD45 or T-cell markers. Another potential source of confusion is the cytoplasmic uptake of serum proteins, such as Igs, by HRS cells.

Table 27-2

ALK, Anaplastic lymphoma kinase; *EBV,* Epstein-Barr virus; *EMA,* epithelial membrane antigen; *MC,* mixed cellularity; *NHL,* non-Hodgkin lymphoma; *NS,* nodular sclerosis; *PCR,* polymerase chain reaction.

The most reliable and most frequently used markers for CHL are the CD30 and CD15 antigens. CD30 is a member of the TNF-nerve growth factor (NGF) receptor superfamily of cytokine receptors.[140] CD30 is expressed in HRS cells in all cases of CHL.[104,112,135,141] Staining is membranous and cytoplasmic, with frequent dot-like accentuation in the perinuclear area, corresponding to the Golgi field (**Fig. 27-5A**). In contrast, the LP cells of NLPBL usually lack CD30 staining, with rare cases showing usually weak and heterogeneous positivity.[142,143] CD30 is expressed in a variety of NHLs, most notably ALCL,[104,112,135,144] but also in a subset of peripheral T-cell lymphoma,[145] NOS, lymphomatoid papulosis and in some large B-cell lymphomas, including PMBL, MGZL, and EBV-positive DLBCL.[146-149] Some non-hematopoietic neoplasms, such as embryonal carcinoma, frequently express the CD30 antigen.[150] Perifollicular blasts in reactive lymph nodes are often positive for CD30 and should not be interpreted as interfollicular HL; their positivity is characteristically more variable than in HRS cells.[151,152]

CD15, detected by LeuM1 or other antibodies, is an antigen of late granulopoiesis and is found in 75% to 85% of CHL cases, although

staining may be weaker than CD30 and restricted to a subset of the neoplastic cells (Figs. 27-4F and 27-5B).[112,135,137,153] The staining pattern is otherwise similar to that of CD30. The reactivity in RS cells is occasionally obscured by large numbers of granulocytes in cases of nodular sclerosis (**Fig. 27-5B**). The expression of CD15 is useful for differentiating HRS cells from CD30-positive reactive blasts or HRS-like cells in conditions such as infectious mononucleosis, which usually are CD15 negative. A notable exception are cytomegalovirus-infected cells, which show CD15 expression and may simulate Hodgkin cells by virtue of their eosinophilic nuclear inclusions.[154] In lymphomas and lymphoproliferations other than CHL, co-expression of CD15 and CD30 is infrequent and mainly observed in MGZL,[149,155-157] some peripheral T-cell lymphomas,[145,158,159] and EBV-associated lymphoproliferations.[92,93,160-162] Not surprising in light of the B-cell derivation of CHL, expression of pan–B-cell markers—mainly CD20—can be found in a percentage of cases of CHL.[77,136,137,163,164] CD20 positivity of RS cells has been reported in <20% to 80% of cases[163] (the difference probably related to technical factors), with the majority of reports being in the 20% to 40% range. In contrast to most B-cell lymphomas, notably T-cell/histiocyte-rich large B-cell lymphoma (THRLBCL) and NLPBL, CHL usually shows weaker staining restricted to a subpopulation of neoplastic cells (**Fig. 27-5C**). CD79a is detected infrequently in CHL,[165] and J chain is always absent.[166,167] The only B-cell–restricted antigen found in the neoplastic cells of virtually all CHLs is PAX5/B-cell–specific activator protein (BSAP), whereas in other B-cell transcription factors, including BCL6, MEF2B, Oct2, BOB.1, and PU.1 are either lacking or only partially expressed.[119,166,168-172] The

expression profile of B-cell transcription factors and B-cell antigens is helpful in the differential diagnosis.[136,173] Nuclear PAX5 (**Fig. 27-5D**) is usually weaker than in reactive B cells, and strong expression of both BOB.1 and Oct-2 is very unusual for CHL and should prompt the consideration of MGZL or DLBCL with CHL-like features in extramediastinal cases.[148,149,157,174] The transcription factor IRF4/MUM-1, a marker of late B-cell differentiation, is usually strongly expressed in CHL in a nuclear fashion (**Fig. 27-5E**) but is also found in ALCL and a subset of DLBCL.[112,130,175] Expression of the germinal-center cell markers “lim domain only 2” (LMO2) and human germinal-center associated lymphoma protein (HGAL) has been found in a subset of CHL cases.[176-178]

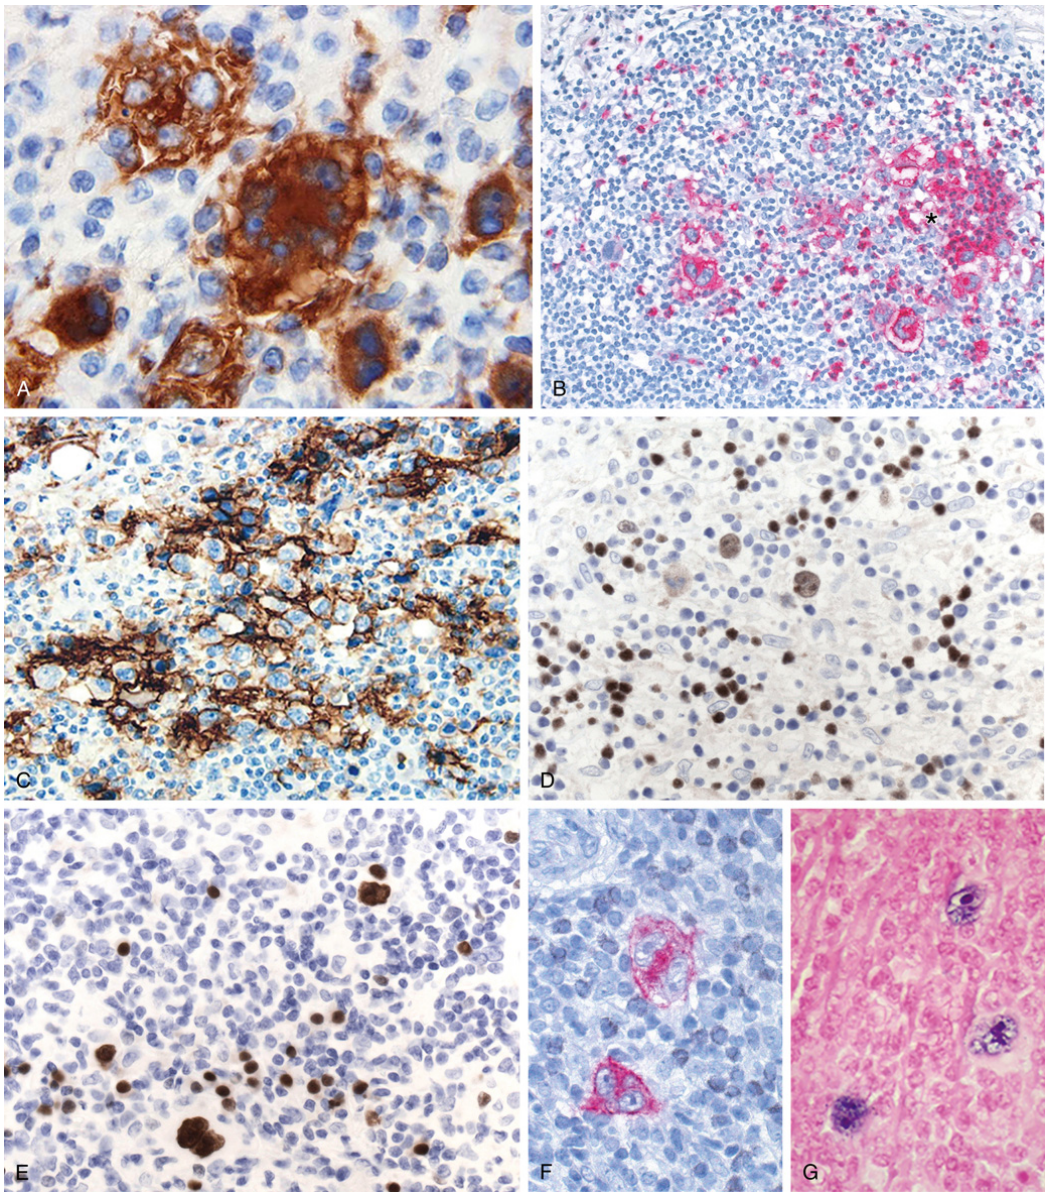

FIGURE 27-5 Immunophenotype of classic Hodgkin lymphoma (CHL).**A,** Strong expression of CD30 in Hodgkin and Reed-Sternberg (HRS) cells and variants in nodular sclerosis CHL. **B,** Expression of CD15 in nodular sclerosis CHL. Note the positivity of neutrophils *(asterisk)*. **C,** CD20 expression in a case of typical nodular sclerosis CHL. Note the variable and incomplete

membranous staining pattern. **D,** PAX5 expression in CHL. The nuclei of the HRS cells typically are weaker than those of the adjacent reactive B cells. **E,** Strong nuclear MUM1/IRF4 expression in HRS cells, equal to that of neighboring plasma cells. **F,** Expression of latent membrane protein-1 (LMP-1) of Epstein-Barr virus (EBV) in mixed cellularity CHL. **G,** RNA in situ hybridization for EBV-encoded RNAs (EBERs) in a case of EBV-positive CHL, with strong nuclear staining restricted to the neoplastic large cells.

Programmed death ligands 1 and 2 (PD-L1/2) are strongly expressed in most cases of CHL through a variety of mechanisms and represent not only an immunohistochemical marker but an important target for immune checkpoint inhibition.[179-182]

Several antigens related to follicular dendritic cells are expressed by HRS cells in varying percentages of cases, among them CD21 and the intermediate filaments restin and fascin.[183-185] The latter is always strongly positive in CHL but lacks specificity.[186]

Positivity of HRS cells for diverse T-cell antigens such as CD2, CD3, CD4, CD45RO, and CD43 has been described in a minority of otherwise typical cases but should not cause concern unless there is absence of PAX5 staining.[138,139] Cytoplasmic staining for the cytotoxic granule-associated proteins TIA-1, granzyme B, or perforin, antigens expressed by activated cytotoxic T cells and natural killer cells and neoplasms derived thereof, is present in approximately 10% to 20% of CHL cases.[187,188] Staining is usually weak and

heterogeneous. However, rare cases with the morphologic features of CHL but that lack PAX5 expression and have variable, sometimes strong expression of cytotoxic molecules are difficult to classify[189]; they, at least in part, more likely represent unusual examples of peripheral T-cell lymphoma or ALCL.[190,191] The T-cell transcription factor GATA3 is expressed in most cases of CHL.[192,193] Epithelial membrane antigen (EMA) and the anaplastic lymphoma kinase (ALK)-1 protein are consistently absent from true CHL.[144,194,195] Absence of the common leukocyte antigen CD45 is a useful diagnostic hallmark of CHL and helps separate it from various NHL mimics and NLPBL.[136,196] The absence of expression of HLA class I antigens, a potential mechanism of immune evasion, is mostly found in EBV-negative CHL.[197]

The LMP-1 protein of EBV is expressed in approximately 25% to 50% of CHLs, depending on histologic subtype and patient characteristics.[12,37,137] The staining is membranous and cytoplasmic, and usually all or most neoplastic cells are positive (**Fig. 27-5F**). ISH for EBERs shows concordance with LMP-1 immunohistochemistry if the nuclear reactivity of HRS cells (and not of rare small lymphocytes) is considered positive (**Fig. 27-5G**).[45] The phenotype of HRS cells is usually constant during the course of the disease. Major variations in antigen expression among multiple biopsy sites or recurrences from the same patient are infrequent.[198]

The reactive background lymphocytes of CHL, with the exception of the nodular pattern of LRCHL, are predominantly T cells. The majority express CD4, belong to the memory compartment, and show signs of activation.[12,13,136,199] The T cells surrounding the neoplastic cells express costimulatory molecules and CD30 and

CD40 ligands, possibly contributing to the survival of the HRS cells.[200] Numbers of CD8-positive cytotoxic T cells are low in CHL, except in patients with HIV infection. A helpful diagnostic criterion is the rarity of CD57-positive T cells in CHL (with some limitation for the nodular variant of LRCHL), in contrast to NLPBL.[77,119] The nodular pattern of LRCHL is characterized by a predominance of B-cell follicles with expanded mantle zones, containing a fine meshwork of dendritic cells. Residual B-cell follicles and follicular dendritic cells can also be identified in a significant percentage of other subtypes, mainly nodular sclerosis CHL.[201]

Genetics and Molecular Findings

Immunoglobulin and T-Cell Receptor Genes

With optimized techniques of single-cell procurement and analysis, HRS cells virtually always contain somatically hypermutated, class-switched, clonally rearranged IGH genes as evidence of their B-cell origin, independent of the expression of B-cell markers.[4,9,202-204] Only rare cases of CHL, even among cases preselected for T-antigen expression, have been shown to contain clonally rearranged T-cell receptor genes.[205,206] As some peripheral T-cell lymphomas may mimic CHL both morphologically and immunophenotypically, attributing cases with rearrangements of the T-cell receptor genes to CHL is controversial. Somehow surprising in light of the molecular findings in primary cases, some of the bona fide CHL-derived cell lines with appropriate gene expression pattern have a T-cell genotype.[7]

Despite the presence of rearranged IG genes and in contrast to NLPBL, CHL lacks BCR and Ig expression on the mRNA and protein

level.[9,13] Several reasons for this lack of Ig transcription have been described. Using single-cell PCR, both so-called “crippling” mutations of the rearranged IGH genes leading to a premature stop codon and mutations of the IG promoter regions have been found, aborting Ig transcription.[207] Interestingly, most cases with crippling mutations are EBV positive, indicating EBV’s role in the survival of these cells. The lack of B-cell surface markers, of the B-cell transcription factors Oct-2 and PU.1, and of the coactivator BOB.1/OBF.1, which are indispensable for IG gene transcription,[171,208] is probably caused by a combination of promoter hypermethylation, epigenetic silencing, and upregulation of ID2 and NOTCH1.[12,13] The lack of Ig transcription indicates a breakdown of the normal regulatory mechanisms of apoptosis in CHL, as Ig expression is a prerogative for the survival of B cells under normal circumstances.

Despite the progress concerning the histogenesis and clonality of CHL, clonality detection only plays a minor role in its practical diagnosis. Although more sensitive techniques such as the BIOMED-2 primer sets can detect B-cell clonality in a significant subset of CHL cases, clonality studies are of limited use in separating CHL from histologic mimics.[209-211] Nevertheless, the presence of a major clonal B-cell or T-cell population, as evidenced by a strong clonal band in PCR, favors a diagnosis of NHL over CHL and can be useful for NHL cases that simulate CHL morphologically, especially some peripheral T-cell NHLs, including ALCL and follicular T-helper cell lymphoma or low-grade B-cell NHL with RS-like cells.[212-214] Next-generation sequencing (NGS)-based detection of B-cell clonality is

more sensitive than conventional techniques and may be useful for the detection of recurrences.[215]

Cytogenetics and Molecular Genetics

Because of the unique cellular composition of CHL and the difficulties in growing HRS cells in culture, cytogenetic examination and molecular studies of CHL using whole tissue extracts have proved difficult until recently. Combining immunophenotypic identification of RS cells and molecular cytogenetics by fluorescence ISH (FISH), chromosomal aberrations and aneuploidy are present in 100% of CHL cases.[216] Although the IGH locus at 14q32 is sometimes involved in translocations in CHL, recurrent translocations typical for NHL are generally absent.[217] Comparative genomic hybridization of isolated HRS cells after random genomic amplification has been used to quantify gains and losses of chromosomal material, leading to the identification of regions of recurrent gains in chromosomes 2p, 7p, 9p, and 11q and losses of 4q and 11q.[218-223] The amplified region on 2p13 contains the *REL* oncogene, which encodes a part of the Rel-A/NF-κB complex, which is constitutively activated in CHL. Further studies revealed common involvement of other chromosomal regions also harboring genes encoding for positive or negative regulators of the NF-κB pathway, including *BCL3* and *MAP3K14*.[223] In addition, the NF-κB inhibitors IκBα, IκBε, and A20 *(TNFAIP3)*, among others, are commonly mutated in CHL, especially in EBV-negative cases.[224-228] The 9p24 region, which is commonly amplified in HRS cells, contains *JAK2* gene and the programmed-death 1 ligand genes *PD1L1* and *PD1L2,* resulting in consistent expression of PD-L1/2.[179,221] In addition,

SOCS1 and *PTPN1,* negative regulators of the JAK/STAT pathway, are inactivated by mutations in subsets of CHL, and gains and activating mutations in *STAT6* are common.[229,230] In addition to PD-L1/2 overexpression, recurrent translocations involving the MHC class II transactivator *CIITA* resulting in downregulation of MHC class II expression and deletions and inactivating mutations in *B2M* and *CD58* support immune evasion by the neoplastic cells.[182] Although p53 protein is frequently expressed by RS cells, mutations of the *TP53* gene are rare, and the same seems true for other examined tumor suppressor genes.[9,12,13]

Studies using comprehensive NGS either on tissue samples, enriched or flow-sorted cells, or cell-free DNA have further elucidated the mutational spectrum of CHL; they have confirmed the importance of genetic alterations leading to activation of NF-κB and JAK/STAT signaling pathways and immune evasion and identified additional recurrent alterations affecting *GNA13,* involved in the PI3K/AKT pathway and also resulting in impaired cytokinesis, likely leading to the formation of RS giant cells, epigenetic regulators (*ARID1A, KMT2D, CREBBP,* and *EP300*), and NOTCH pathway members.[231-233]

Despite the increase in knowledge regarding CHL genetics, mutational analysis does not currently play a role in tissue diagnostics. It remains to be seen which role molecular profiling either of tissue biopsies or cell-free DNA will play in the future for diagnosis and follow-up.[234]

Gene Expression Profile and Activated Signaling Pathways

Large-scale screening strategies have been used to study the expression profile of CHL-derived cell lines or primary HRS cells.[62,235] Despite the presence of clonal IGH gene rearrangements in CHL, the downregulation of most B-cell antigens and the virtual lack of a B-cell–specific gene expression profile justify the separation of CHL from B-cell lymphoma.[235-237] In part, this phenotype is caused by epigenetic silencing of B-cell–specific master transcription factors through promoter region methylation.[238] Furthermore, deregulated expression of genes involved in T-cell differentiation such as *NOTCH1* and *GATA3* further contribute to loss of the B-cell signature.[12,192,239,240] The survival of the neoplastic cells of CHL despite the lack of a functional B-cell receptor and B-cell program indicates a profound deregulation of apoptotic pathways, which is also evidenced by the constitutive expression of antiapoptotic proteins such as BCL2, BCLxL, and c-FLIP.[9,241] The current hypothesis on CHL pathogenesis postulates that HRS cells are rescued by constitutive activation of diverse signaling pathways through somatic mutations, EBV, and microenvironmental signals.[12,137] Therefore, not surprisingly, expression profiling of CHL shows significant differences with most B-cell neoplasms, with the exception of PMBL and MGZL, entities exhibiting both morphologic, phenotypic, and genotypic overlap with CHL.[242-245] Of interest, gene expression profiling of microdissected HRS cells not only confirmed the profound differences between CHL and other B-cell neoplasms, but it also demonstrated that bona fide Hodgkin cell lines and microdissected HRS cells are very similar in their hallmark features but nevertheless show significant transcriptional

differences, probably reflecting the importance of the inflammatory microenvironment in primary cases.[62]

A central feature of CHL is the constitutive activation of the NF-κB pathway.[13,246-248] Signaling through members of the TNF-NGF receptor superfamily expressed by RS cells, such as CD30, CD40, and LMP-1, activates a complex intracellular signaling cascade involving TRAF1 and 2 (among other molecules), ultimately leading to NF-κB activation. The constitutively activated Rel-A/NF-κB complex induces transcription of various genes thought to play an important role in the evasion of apoptosis, survival, and proliferation of HRS cells.[8,13] Of note, constitutive NF-κB activation is achieved through different pathways in EBV-positive and EBV-negative cases, as evidenced by the much higher frequency of genetic alterations affecting NF-κB pathway genes such as A20/*TNFAIP3* in the latter group.[12,224,228]

In addition to the genetic lesions described herein, constitutive activation of the JAK/STAT pathway with downstream phosphorylation of STATs is caused also by autocrine and paracrine stimulation and the aberrant activation of a variety of receptor tyrosine kinases. Further signaling cascades with deregulated activity include the NOTCH-1, PI3K/AKT, and MAPK/ERK pathways.[9,13,248]

Role of the Microenvironment in Classic Hodgkin Lymphoma

The intense inflammatory response typical of CHL points to the involvement of disturbed immunologic pathways in disease pathogenesis and underlines the importance of the tumor microenvironment (TME).[199,249-251] As lymphoid cells in a constant

state of activation, the neoplastic cells of CHL influence their surroundings with a wide range of secreted cytokines and chemokines; however, they themselves also depend on the crosstalk with reactive cell populations.[252] Among the substances produced by HRS cells, or in part by the accompanying reactive infiltrate, are TNF-α, transforming growth factor-β (TGF-β), interferon-γ, IL-2, IL-5, IL-6, IL-8, IL-9, IL-10, IL-12, and IL-13, in addition to the chemokines eotaxin, thymus and activation-regulated chemokine (TARC), macrophage inflammatory protein (MIP1α), and others.[12,199,252] The majority of factors attract and activate TH2 cells and may contribute to a local suppression of cytotoxic T cells. IL-5 and eotaxin are likely responsible for tissue eosinophilia.[199,253] TGF-β, found predominantly in nodular sclerosis CHL, is immunosuppressive and induces fibroblast proliferation and collagen formation, characteristic of this subtype.[254] The expression of some cytokines, such as IL-10, correlates with the EBV status of the disease.[255] In addition to attracting and modulating the inflammatory infiltrate and providing growth and survival stimuli to the neoplastic cells, the secreted cytokines are probably one of the reasons for the frequent presence of systemic symptoms. In addition to secreting cytokines favoring an immunosuppressive microenvironment and downregulation of HLA class I and II molecules, HRS cells exhibit additional mechanisms of immune evasion, including overexpression of FAS ligand (CD95L), Galectin-1, and the coinhibitory PD1/PD-L1/PD-L2 axis, all of which result in T-cell exhaustion, abrogating an efficient T-cell response.[199,248] Although previously thought to be dominated by CD4-positive TH2 cells, studies have identified CD4-positive/LAG3-positive type-I

regulatory T cells and PD1-positive TH1 cells as major immunosuppressive TME components characteristic of CHL.[249-251] As evident from morphology, the TME varies greatly with subtype, with implications for its prognostic role, but is also likely influenced by the genetic profile and the host immune system.

Postulated Cell of Origin

For most cases of CHL studied by single-cell analysis, the presence of clonally rearranged, somatically mutated IG genes indicates a derivation from germinal-center B cells incapable of Ig transcription. However, the virtual lack of a B-cell expression profile underlines that the sum of genetic alterations of a neoplastic cell rather than its origin shapes its phenotype and clinical behavior.

Clinical Course and Prognostic Factors

The clinical course and prognosis of CHL have changed dramatically since the introduction of radiotherapy and multimodal chemotherapy. The natural history of the disease is characterized by slow but relentless tumor progression with extensive organ involvement, and in the past, many patients succumbed to infectious complications. Today, the overall cure rate for all patients is around 80% for advanced stages and >90% for limited disease. Current therapeutic approaches combine less toxic, abbreviated chemotherapy regimens with involved field radiotherapy for early-stage disease.[17,256,257] The rationale of this approach is to reduce the frequency of late complications of radiotherapy without compromising the excellent cure rates.[17,99,258] FDG PET/CT is increasingly used to avoid radiotherapy in patients with complete

metabolic response. Multiagent chemotherapies such as ABVD (Adriamycin [doxorubicin], bleomycin, vinblastine, dacarbazine) or newer regimens are the mainstay of treatment for advanced-stage HL. High-dose chemotherapy with autologous stem-cell transplantation can be administered successfully to patients with primary progressive disease or early relapse who have an extremely poor prognosis with conventional chemotherapy.[17] New drugs, especially the anti-CD30 antibody-conjugate brentuximab vedotin and blockade of PD-1 signaling with nivolumab or pembrolizumab, show significant activity also in refractory patients and herald a new era for targeted therapy in CHL.[259,260]

Given the high cure rate, complications of therapy, especially second malignancies, have gained importance. Patients cured of CHL have a significantly increased risk of secondary cancers, which are the main cause of death in long-term survivors.[261-263] Although common solid tumors are the most frequently encountered malignancies, the greatest increase in incidence is observed for acute nonlymphocytic leukemias, mainly as a result of alkylating agents. The cumulative incidence of secondary NHL after CHL is approximately 1% according to recent results—a lower rate than in earlier studies. The majority of cases are DLBCLs, frequently at extranodal sites.[264,265] In general, the prognosis of secondary malignancies is poor.

In the last decades, a vast number of clinical features and serum and tissue biomarkers associated with clinical outcome have been described. Stage is the most important single prognostic factor in CHL, with Ann Arbor stages I and II designated as limited stage disease (without or with risk factors) and III and IV as advanced

stage disease. Nevertheless, in more than half the patients with stage IV disease, complete remission can be achieved and is durable in a significant fraction of them.[99,258] Other clinical parameters of adverse prognostic significance include age, male sex, bulky mediastinal disease, liver involvement, anemia, leukocytosis, lymphopenia, hypoalbuminemia, and elevated lactate dehydrogenase.[266-268] For advanced disease, the International Prognostic Factor Project has developed a prognostic scoring based on these parameters that identifies patients at high risk of progression.[266] Bone marrow involvement per se does not confer a worse prognosis compared with other patients with advanced disease.[75] Serum surrogates of disease activity, such as increased levels of TARC, soluble CD30, IL-2, and IL-6 have prognostic relevance, with serum TARC always increased at baseline and correlated with treatment response.[199,269] An important new prognostic factor is the use of PET/CT to evaluate the response to chemotherapy.[270] In contrast, the effect of histologic subtype and histologic grade in nodular sclerosis CHL has diminished.

A number of tissue-based features have been analyzed for their potential prognostic relevance, including expression of CD15, CD20, and BCL2 and EBV status of the neoplastic cells, with often conflicting results.[136,199] PD-L1 expression on HRS cells predicts response to checkpoint inhibition in relapsed/refractory CHL.[181] The composition of the background infiltrate, including T-cell subsets, macrophages and their polarization, eosinophils, mast cells, follicular dendritic cells, and B cells, has been scrutinized in many studies. Although the presence of increased numbers of macrophages and activated cytotoxic T cells has been most consistently associated

with a worse prognosis, the best way to assess the microenvironment and its relevance is an unresolved issue.[136,199] Other approaches for separating prognostic groups, such as gene expression profiling, which has identified a macrophage signature associated with adverse treatment outcome, microRNA profiling or proteomic analysis have not entered into clinical decision making.[99,136,271]

Related Lesions and Differential Diagnoses

Although most cases of CHL can be safely classified on the basis of morphology and immunohistochemical features, distinction from various subtypes of NHL, reactive disorders, or even non-hematopoietic neoplasms can prove difficult. Some lymphoid neoplasms show a significant morphologic and phenotypic overlap with CHL, occasionally making a clear distinction impossible. A fraction of these lesions represents true borderline cases between CHL and NHL, namely MGZLs,[148,149,157,174,272] whereas others are mere morphologic and/or phenotypic mimics. A broader group of NHLs may contain HRS-like cells and may exhibit a pattern reminiscent of the reactive inflammatory background of CHL. However, immunohistochemical stains usually make the neoplastic character of the background population in these cases readily apparent. Furthermore, HRS-like cells can occur in reactive disorders or even neoplasms of nonlymphoid origin and may lead to diagnostic difficulties, especially in small biopsy specimens.

Mediastinal (Thymic Niche) Gray-Zone Lymphoma

Given the B-cell origin of CHL, it is not surprising that cases with hybrid features between large B-cell lymphoma and CHL can be observed.[148,149,155,156,273] Since the introduction of the concept of "B-cell lymphoma unclassifiable, with features intermediate between DLBCL and CHL (gray zone lymphoma)" in the 2008 World Health Organization (WHO) classification, the definition of gray-zone lymphoma has evolved significantly in the light of new genetic information documenting that MGZLs occupy a truly intermediate position between PMBL and NSCHL, whereas extramediastinal cases with overlapping morphology and immunophenotype are more similar to conventional DLBCL or EBV-positive DLBCL, NOS, respectively. Therefore, both the ICC and the 5th edition of the WHO classification have now accepted the entity MGZL, excluding extramediastinal cases.[11,105]

Clinical Features

MGZL most commonly affects males in the 3rd to 4th decades of life and presents with bulky disease and occasional involvement of supraclavicular lymph nodes. It can spread to supraclavicular nodes and the lung, spleen, and bone marrow, whereas involvement of unusual extranodal sites as in PMBL is rare. MGZL shows a worse clinical outcome than both CHL and PMBL.[146,174] Regimens for aggressive B-cell lymphomas have been used successfully in MGZL.[274]

Morphology and Immunophenotype

MGZL usually shows asynchrony between morphology and immunophenotype, which may present in two ways: Some cases show morphology of CHL of nodular sclerosis type but have a

preserved B-cell program with increased expression of a variety of B-cell markers, including strong and homogeneous expression of CD20 and/or CD79a, frequent positivity for the transcription factors BOB.1 and Oct-2, variable BCL6 reactivity, and common loss of CD15 (**Fig. 27-6**). The second group of cases exhibit a diffuse proliferation of large cells, which in addition to B-cell marker expression show strong and homogeneous CD30 positivity and often CD15 positivity.[148,155,157,273,275,276] Overall, most cases of MGZL have evidence of a clear B-cell phenotype with expression of more than one B-cell marker. Aberrant expression of single markers normally does not justify inclusion in the MGZL category. Of note, rare EBV-positive cases of MGZL with otherwise typical phenotypic and molecular features have been observed.[157,277] The intermediate position of MGZL between PMBL and CHL is also evident on the molecular level. Translocations involving the MHC class transactivator CIITA and amplifications of *REL* (2p15) and *JAK2* (9p24) oncogenes and mutations of *SOCS1, B2M, TNFAIP3, GNA13, STAT6,* and *NFKBIA* are commonly observed in all three entities.[275,277,278] Comparative gene expression profiling demonstrated an intermediate score for MGZL, with cell cycle and extracellular matrix-related genes reflecting cell density and microenvironment.[243,279] Similarly, the methylation profile of MGZL is intermediate between CHL and PMBL, further documenting that it represents a related but distinct lymphoma subtype.[278]

Patients with features of a composite lymphoma, with both morphologically and immunologically typical nodular sclerosis CHL and PMBL in different areas of the same biopsy, must be diagnosed

as such, indicating both histologic components, and should not be diagnosed as MGZL.[280] These two components may also be diagnosed sequentially at different times, suggesting phenotypic plasticity of the neoplastic clone.

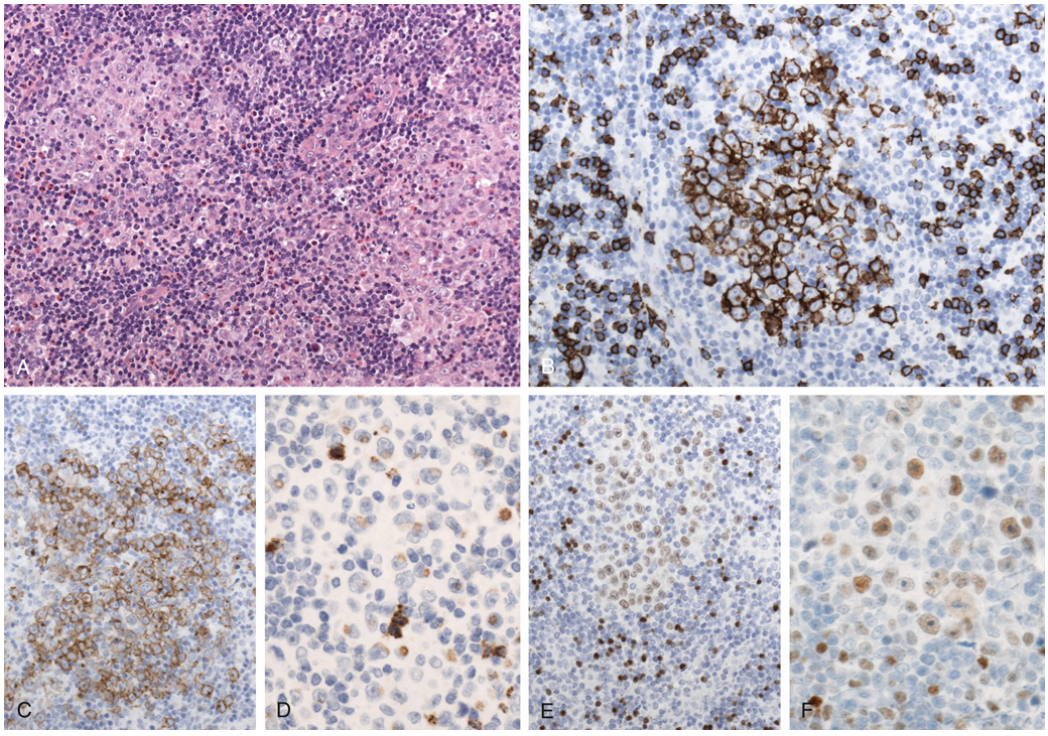

FIGURE 27-6 Mediastinal gray-zone lymphoma.**A,** Relatively compact nodules of large cells with prominent nucleoli, resembling Hodgkin cells admixed with occasional Reed-Sternberg (RS)-cells and many eosinophils and small lymphocytes. **B,** Strong and homogeneous expression of CD20 and **(C),** CD30. **D,** CD15 is heterogeneously, but distinctly expressed in a perinuclear fashion. **E,** PAX5 expression is attenuated. **F,** Oct-2 is heterogeneously positive in the neoplastic cells.

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

The differentiation of CHL from conventional extramediastinal DLBCL is usually straightforward by morphology and is easily confirmed by immunohistochemistry, even in cases with occasional HRS-like giant cells in a background of more conventional immunoblasts or centroblasts. However, some subtypes of DLBCL may occasionally exhibit close morphologic and phenotypic overlap with CHL but are not considered to be biologically related to CHL, in contrast to MGZL.[11,104,157] Genetic studies have shown that extramediastinal large B-cell lymphomas with Hodgkin-like features are distinct from MGZL and PMBL, with occurrence of *BCL2* and *BCL6* translocations and mutations frequently encountered in conventional DLBCL and a gene expression profile more closely related to DLBCL.[277,279]

Although these cases may show abundant HRS-like cells and an inflammatory background simulating CHL, they usually exhibit a broader cytologic range of atypical large cells with positivity for several B-cell markers, including strong CD20 and/or PAX5 expression.

T-cell and histiocyte-rich large B-cell lymphoma (THRLBCL) is a DLBCL characterized by a minority of large blasts of B-cell origin in a background of reactive T cells and histiocytes and is thought to be related to NLPBL. THRLBCL usually exhibits a diffuse growth pattern. Sometimes, the tumor cells may resemble classic HRS cells, but a resemblance to LP cells is more common (**Fig. 27-7A**). The neoplastic cells of this tumor usually stain strongly for CD20 and other B-cell markers, in addition to BCL6 (**Fig. 27-7B**); they frequently express EMA but usually lack CD30 and CD15 (**Table 27-3**).[104,281-283]

EBV-Associated B-Cell Lymphoproliferations and Lymphomas

EBV-Positive Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

EBV-positive DLBCL, NOS may closely simulate CHL but usually shows a broad cytologic spectrum with more abundant neoplastic cells. They show variable, frequently strong expression of B-cell markers, with common positivity for CD30 and CD15 expression in 23% to 68% of cases. LMP1 expression in EBV-positive DLBCL can be heterogeneous and lacks the clear dichotomy between LMP1-positive HRS cells and a negative inflammatory background of EBV-positive CHL.[160,284-287] EBNA-2 expression, which occurs in a minority of EBV-positive DLBCL, rules out a diagnosis of CHL. The genetic profile of EBV-positive DLBCL, NOS is distinct both from CHL and conventional DLBCL.[277] Clinically, isolated extranodal presentation of an EBV-positive lymphoproliferation with Hodgkin-like features argues strongly against a CHL diagnosis.

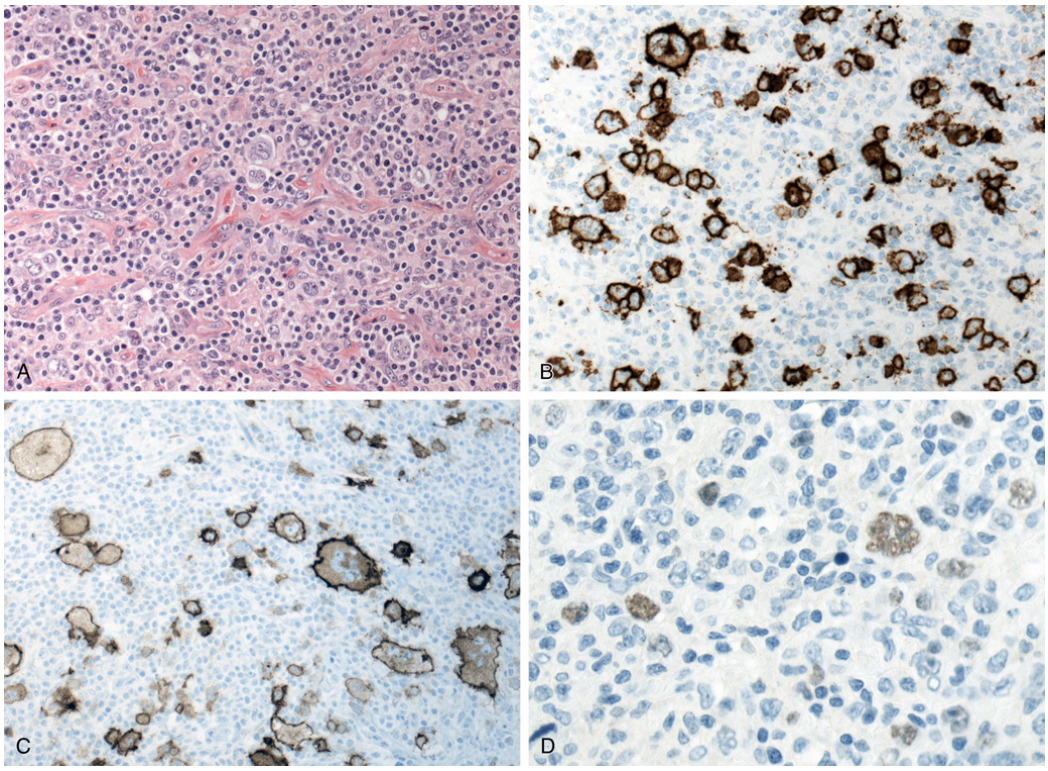

FIGURE 27-7 EBV-positive diffuse large B-cell lymphoma, not otherwise specified.**A,** HRS-like cells and mononuclear large cells are intermingled with small lymphocytes and occasional eosinophils. The atypical cells stain strongly and homogeneously for CD20 **(B)** and CD30 **(C)**. Some tumor cells express the EBNA2 antigen of EBV **(D)**, indicative of latency pattern III, which is incompatible with a diagnosis of CHL.

Other EBV-Associated Lymphoproliferative Disorders

EBV-associated LPDs arise most frequently in the setting of immunodeficiency or iatrogenic immunosuppression or immunosenescence but may also occur without evident immune

defects. They show a broad clinical and morphologic spectrum and may simulate CHL morphologically and phenotypically. CHL-like EBV-positive LPDs consist of a polymorphous proliferation of small-to-large lymphoid cells with frequent RS-like cells. Morphologically, RS-like cells in CHL-like posttransplant LPD or iatrogenic LPD are part of a continuum of lymphoid cells in various stages of transformation rather than embedded in a reactive background of small lymphocytes (**Fig. 27-7D**).[288] They usually co-express CD30 and CD20 but are CD15 negative and show EBV positivity frequently with latency type III expressing EBNA2, in contrast to CHL.[93,289-291] True CHL can also occur in the posttransplant setting and simulates sporadic CHL morphologically and phenotypically; it occurs late after transplantation and usually does not respond to a reduction in immunosuppression.

Mucocutaneous Ulcer

EBV-associated mucocutaneous ulcers also frequently show presence of HRS-like cells but can be separated from CHL based on its primary extranodal manifestation, the presence of a polymorphic background population, the common co-expression of B-cell antigens in the HRS-like cells, and the demarcation of the lesion by a cuff of T cells.[92,93]

Nodular Lymphocyte-Predominant B-Cell Lymphoma

Separation of NLPBL and LRCHL may sometimes be difficult (also addressed in this chapter's section on LRCHL). NLPBL is characterized by nodular structures reminiscent of progressively transformed germinal centers, whereas the nodules in LRCHL

consist of expanded follicle mantles with atrophic or residual germinal-center remnants.[77,282,283,292,293] The morphology of the neoplastic cells is of limited value because tumor cells with LP morphology can occur in both entities, so immunophenotyping is of paramount importance for the differential diagnosis. Strong and homogeneous expression of CD20, CD79a, J chain, and B-cell transcription factors Oct-2, BOB.1, BCL-6, and myocyte enhancer factor 2B (MEF2B), in addition to expression of EMA and CD45, supports a diagnosis of NLPHL, whereas the neoplastic cells of LRCHL are usually positive for CD30 and CD15 and may be infected with EBV.[166,293] The small numbers of CD30-positive blasts frequently observable in NLPHL more commonly represent non-neoplastic perifollicular immunoblasts rather than LP cells, but a fraction of otherwise classic NLPHLs show CD30-positive tumor cells.[142,143] Of note, rare cases of otherwise classic NLPBL showing EBV positivity or CD15 expression of the neoplastic cells have been described.[119,294,295] In these cases, preservation of the B-cell program is the clue to the correct diagnosis. Of note, LRCHL shows a higher incidence of expression of B-cell transcription factors than other CHL subtypes.[119] Both entities usually show a predominance of B cells in the background population and contain follicular dendritic cell networks. Although increased numbers of CD57-positive/PD1-positive T cells forming rosettes are characteristic of NLPBL, they may also be observed in LRCHL, potentially suggesting a relationship between these two entities (**Table 27-4**).[77,104,112,119]

* Rare cases of NLPBL with expression of CD30, CD15, or EBV positivity described.

Anaplastic Large Cell Lymphoma

ALCL, initially identified by virtue of its strong reactivity with antibodies against CD30, shows some morphologic and phenotypic similarities to CHL.[144,296,297] Tumor cells of ALCL may resemble RS cells or mononuclear variants, but they are usually smaller than the neoplastic cells of CHL and often show bean-shaped or horseshoe-shaped nuclei ("hallmark" cells). Furthermore, ALCL usually grows in cohesive sheets and frequently involves lymph node sinuses—rare features in CHL. Immunophenotypically, expression of T-cell antigens, cytotoxic molecules, EMA, ALK-1 protein, and CD45 supports a diagnosis of ALCL, whereas expression of CD15, CD20, and PAX5 suggests CHL (**Table 27-5**). MUM1/IRF4 expression is not contributory, because it occurs in both entities. Of note, rare cases of ALK-negative ALCL with PAX5 expression and extra copies

of the *PAX5* locus have been described.[298] The presence of a prominent clonal T-cell rearrangement or t(2;5) excludes CHL.[296,297] Rare cases of ALK-positive ALCL with a nodular growth pattern strongly resemble nodular sclerosis CHL, and they are readily diagnosed with immunohistochemical studies because they lack PAX5 and CD15 but may express T-cell markers.[299]

CHL PAX5-Negative With Expression of Cytotoxic T-Cell Markers Versus CHL-Like ALK-Negative ALCL

Although expression of T-cell markers can occasionally be encountered in otherwise typical CHL,[138,139] rare lymphoma cases with CHL morphology and strong CD30 and CD15 positivity may show strong expression of one or several cytotoxic granule markers, including TIA-1, granzyme B, and perforin, usually associated with complete absence of PAX5 expression.[189] Some of these cases were found to relapse as conventional peripheral T-cell lymphomas,[191] indicating some of these cases might represent PTCL with Hodgkin-like features. Furthermore, cases of CHL-like CD30-positive PTCL harboring *JAK2* rearrangements have been described.[190]

Table 27-5

Differential Diagnosis: Classic Hodgkin Lymphoma (CHL) and Anaplastic Large Cell Lymphoma (ALCL)

	CHL	ALCL
Architecture	Nodular or diffuse	Mostly diffuse, dominance of large cells, sinus involvement
Neoplastic cells	Classic HRS cells, lacunar cells,	Mononuclear cells predominate, "hallmark" cells, some RS-like cells
Phenotype	$CD30^{+}$, $CD15^{+}$, $CD20^{-/+}$, LMP-$1^{+/-}$, $PAX5^{+}$ (weak), T-cell markers usually negative, $ALK1^{-}$, EMA^{-}	$CD30^{+}$, $CD15^{-/+}$, $CD20^{-}$, $CD4^{+}$, $CD45^{+/-}$, LMP-1^{-}, $PAX5^{-}$*, T-cell markers often positive, $ALK1^{+/-}$, EMA^{+}, cytotoxic markers
Genotype	Usually polyclonal (B and T cells), minority shows B-cell clonality	Clonal T-cell rearrangement (80%-90%)

ALK, Anaplastic lymphoma kinase; *EMA,* epithelial membrane antigen; *LMP,* latent membrane protein; *RS,* Reed-Sternberg

* Rare cases positive.

Other Subtypes of Non-Hodgkin Lymphoma and Composite Lymphomas

RS-like cells can occur in a wide range of NHLs of both B-cell and T-cell types. Among B-cell lymphoid neoplasms, this phenomenon is most frequently encountered in chronic lymphocytic leukemia (CLL). In most cases, RS-like cells are present singly or in small clusters in the background of morphologically and phenotypically classic CLL ($CD5^+$, $CD20^+$, $CD23^+$). They frequently express CD30 and sometimes CD15, may co-express CD20, and are usually infected by EBV ($EBER^+$, $LMP\text{-}1^+$).[300-302] These cases may represent precursor lesions for CHL, which has an increased incidence in patients with CLL and occasionally presents as a composite lymphoma.[303] A clonal relationship between the two populations has been shown for some, but not all, cases studied by single-cell PCR.[304,305] These cases arise more commonly from CLL with mutated IG genes and seem to carry a better prognosis than conventional Richter transformation but similar to CHL arising in CLL.[300,303] Some of the EBV-positive cases have been observed under fludarabine treatment, thus showing resemblance to EBV-associated CHL-like B-cell LPD in immunosuppressed patients.[306]

Transformed B cells with RS-like morphology and true composite lymphomas with separate areas of both CHL and B-cell NHL have also been observed in other B-cell NHL subtypes, most frequently follicular lymphoma.[202,307] In some cases, a common clonal origin has been demonstrated by molecular studies.[308]

Peripheral T-cell lymphomas frequently show a polymorphic inflammatory background with eosinophils, neutrophils, plasma cells, and histiocytes and may contain RS-like giant cells (**Fig. 27-8**). In some neoplasms, such as nodal peripheral T-cell lymphoma, NOS, transformed mycosis fungoides, and nodal involvement by CD30-positive LPDs of the skin, RS-like cells show co-expression of CD30, CD15, and T-cell markers and probably represent transformed cells of the malignant clone. Usually, they form part of a continuum of small to medium-sized and large blasts.[145,158] In contrast, RS-like cells in follicular T-helper cell lymphomas and adult T-cell lymphoma/leukemia are commonly, but not always, EBV transformed, nonclonal B cells and are probably the result of an underlying local immune dysregulation (**Fig. 27-8C**).[213,214,309,310] Because the background population of neoplastic T cells in cases of T-cell NHL with RS-like giant cells can sometimes show only minimal cytologic atypia, as in cases of follicular T-helper cell lymphomas, detailed immunophenotyping and molecular studies may be necessary for distinction from CHL.[212] Another pitfall is the occurrence of HRS-like cells with CD30 and sometimes CD15 expression in draining lymph nodes of patients with CD30-positive cutaneous LPDs or mycosis fungoides.[158,311]

Reactive Disorders

Reactive lymphadenopathies with a wide range of both infectious and noninfectious causes can exhibit HRS-like cells. Infectious mononucleosis typically shows florid interfollicular hyperplasia, with at least partial preservation of the lymph node architecture. The paracortical proliferation may be dominated by variously sized

immunoblasts or show a mixed cytology, with small lymphocytes and interspersed, frequently binucleate blasts closely resembling RS cells. Necrosis may be present. The clinical picture and serologic findings are crucial in avoiding a misdiagnosis of CHL in such cases. Morphologically, the range of cell sizes and the marked cytoplasmic basophilia of many blasts are indicators of a reactive disorder.[312] HRS-like cells in infectious mononucleosis can express CD30, LMP-1, and partly EBNA-2, but they lack CD15 and frequently show CD20 expression.

Other lymphadenitis forms of viral or unknown cause may occasionally mimic CHL, especially the interfollicular growth pattern. As in infectious mononucleosis, these cases can show prominent expression of CD30 with variable downregulation of B-cell transcription factors such as PAX5, but they lack CD15 expression—with the exception of cytomegalovirus lymphadenitis—and express polyclonal Ig light chains.[152,154]

Neoplasms of Nonlymphoid Origin

A large number of nonlymphoid neoplasms may resemble CHL morphologically, especially if only small biopsy specimens are available. In most instances, immunohistochemical studies resolve these cases. However, one should be aware of the potential pitfalls of a limited antibody panel. Both CD15 and CD30 can be expressed by a range of non-hematopoietic neoplasms. Lymph node metastasis of large cell undifferentiated carcinoma or melanoma may resemble the syncytial variant of nodular sclerosis CHL (**Fig. 27-8E**), but it is usually easily differentiated by appropriate immunostainings for cytokeratins or S-100 protein and melanoma antigens, respectively.

Undifferentiated nasopharyngeal carcinoma can resemble CHL both morphologically and clinically because the tumor frequently presents with cervical lymph node metastasis, whereas the primary tumor is often clinically unapparent. Extragonadal germ-cell tumors can simulate NSCHL with a mass lesion in the anterior mediastinum. The neoplastic cells of seminoma may resemble lacunar cells and sometimes exhibit a nodular growth pattern with concentric fibrosis, but demonstration of PLAP (placenta-like alkaline phosphatase), OCT-4, and CD117 positivity resolves these cases. Inflammatory variants of sarcomas may contain RS-like cells, but these usually do not pose major diagnostic problems.

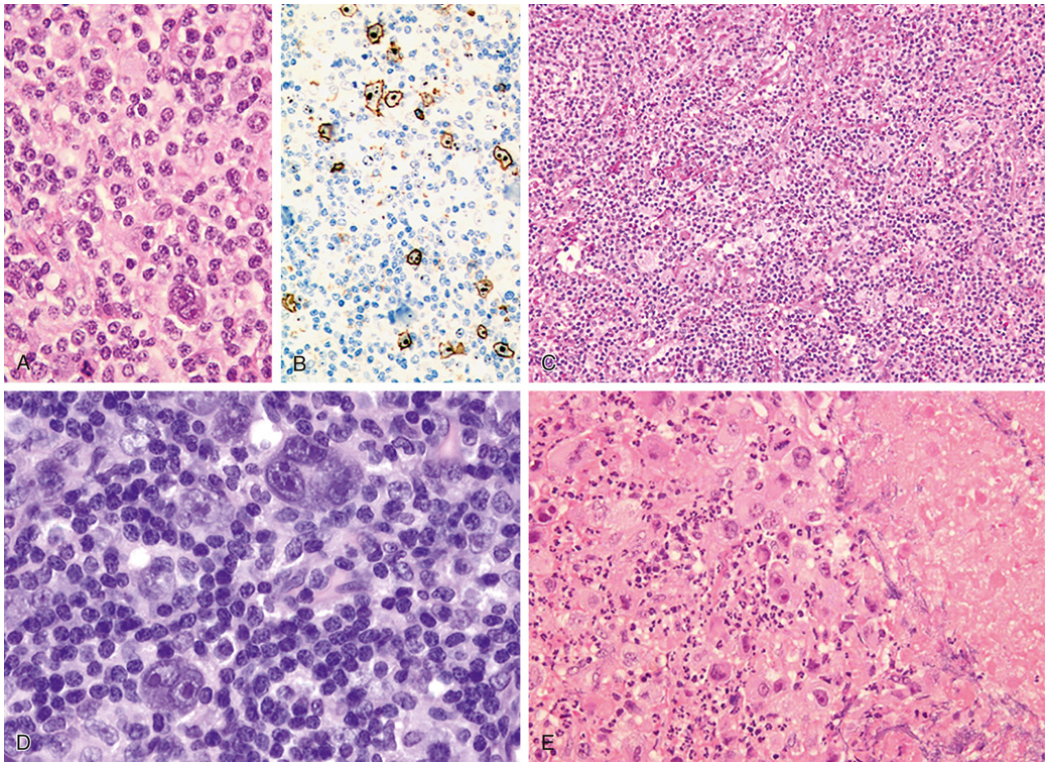

FIGURE 27-8 Differential diagnosis of classic Hodgkin lymphoma (CHL).**A,** T-cell/histiocyte-rich large B-cell lymphoma with Reed-Sternberg (RS)–like cells. **B,** Tumor cells show strong and homogeneous staining for CD20 and lack CD30 and CD15. **C,** Follicular helper T-cell lymphoma angioimmunoblastic type, with occasional Epstein-Barr virus (EBV)-positive RS-like cells *(arrows)* of B-cell phenotype ($CD20^+$, $CD30^+$). **D,** Hodgkin-like posttransplant lymphoproliferative disorder with occasional RS cells in a polymorphous B-cell proliferation. **E,** Mediastinal lymph node biopsy of anaplastic large cell carcinoma with occasional RS-like cells.

Pearls and Pitfalls

- Diagnosis of CHL requires the presence of HRS cells in the appropriate cellular background. Many reactive and neoplastic disorders can mimic CHL.
- Joint expression of CD30 and CD15, although highly characteristic of CHL, can rarely be seen in other neoplasms, including both aggressive B-cell and T-cell lymphomas and EBV-associated LPDs.
- Nodular sclerosis CHL is distinct from other forms of CHL in terms of its demographics and epidemiology, whereas the mixed cellularity and lymphocyte-depleted subtypes show similar features.
- LRCHL most often has a nodular growth pattern and may show morphologic and immunophenotypical overlap with NLPBL.
- CHL is a B-cell neoplasm in which the B-cell program is highly suppressed. In cases with CHL-like morphology but strong, homogeneous expression of B-cell markers, alternative diagnoses need to be considered, depending on location and EBV status. These include MGZL, EBV-positive DLBCL, DLBCL, NOS, and EBV-positive LPD.

Chapter 28: Virally Associated B-Cell Lymphoproliferative Disease

Alina Nicolae, Stefania Pittaluga, and Jonathan W. Said

OUTLINE

Ebv-Associated Lymphoproliferative Disorders

- **Epstein-Barr Virus Life Cycle and Pathogenesis**
- **Epstein-Barr Virus–Positive Mucocutaneous Ulcer**
- **Epstein-Barr Virus–Positive Diffuse Large B-Cell Lymphoma, NOS**
- **Diffuse Large B-Cell Lymphoma Associated With Chronic Inflammation**
- **Fibrin-Associated Diffuse Large B-Cell Lymphoma**
- **Lymphomatoid Granulomatosis**

Epstein-Barr Virus–Positive Polymorphic B-Cell Lymphoproliferative Disorder, NOS

HHV-8-Associated Lymphoproliferative Disorders

HHV-8 Life Cycle and Pathogenesis

Multicentric Castleman Disease

HHV-8-Positive Germinotropic Lymphoproliferative Disorder

HHV-8-Positive Diffuse Large B-Cell Lymphoma, NOS

Primary Effusion Lymphoma

Extracavitary Primary Effusion Lymphoma

Kaposi Sarcoma Involving Lymph Nodes

Epstein-Barr virus (EBV) and Kaposi sarcoma-associated herpesvirus/human herpesvirus 8 (KSHV/HHV-8) are gamma herpesviruses that can infect B lymphocytes. Both establish a latent infection in which no viral progeny is usually produced and only a limited number of genes are expressed. Despite their tumorigenicity, most infected individuals carry a persistent silent infection. In certain settings, mainly of immune deficiency/dysregulation (e.g., inborn error of immunity, iatrogenic/therapy-related, posttransplant, HIV infection, autoimmune disease, or immune senescence), an increased risk for developing EBV or HHV-8-related

lymphoproliferative disorders (LPDs) is observed. These LPDs show significant morphologic similarities and, to a certain extent, biological overlap across various immune impairment backgrounds. The pathologic spectrum of virally associated B-LPD is broad, ranging from benign lymphoid hyperplasia to aggressive lymphomas. Their defining feature consists in the identification of EBV or HHV-8 in most atypical lymphoid cells in tissue sections. Often, the virally associated reactive processes can mimic lymphomas, given the clinicopathologic changes mediated by the virus itself and the immune reaction generated. In such situations, a multidisciplinary approach is essential to achieve an accurate diagnosis and to establish the optimal therapy.

This chapter focuses mostly on the EBV- or HHV-8-associated LPDs in noniatrogenic settings. The EBV-related lymphoid proliferations and lymphomas associated with inborn and iatrogenic immune deficiency/dysregulation are further addressed in **Chapters 53** and **54**. In addition, well-defined B-cell lymphoma entities associated with EBV such as Burkitt lymphoma, plasmablastic lymphoma, and classic Hodgkin lymphoma are discussed in **Chapters 23**, **24**, and **27**, respectively. Finally, **Chapter 29** expands on EBV-associated T- and NK-cell lymphoid proliferations.

Ebv-Associated Lymphoproliferative Disorders

Epstein-Barr Virus Life Cycle and Pathogenesis

EBV Life Cycle

EBV, also known as human herpesvirus 4 (HHV-4), is a double-stranded DNA γ-herpesvirus. It was the first tumor virus identified in humans, within Burkitt lymphoma cells, by Epstein et al. in 1964.[1] There are two EBV genotypes (types 1 and 2) encompassing 71 strains (60 type 1 and 11 type 2) with variation mainly in the latent genes.[2-4] EBV is ubiquitous, with approximately 95% of the world's population sustaining a lifelong asymptomatic infection.[5,6] The virus is orally transmitted via saliva exchange and reaches the submucosal secondary lymphoid tissues (i.e., tonsils) through epithelial transcytosis. It commonly infects B lymphocytes, and less commonly epithelial, mesenchymal, T, and NK cells. In healthy carriers, the EBV life cycle is mostly confined to the B cells and it is biphasic, with phases of lytic replication and latency, which can go from III to II to 0 to I (**Fig. 28-1**).[7,8] The EBV genome does not integrate into the host genome and it is linear during replication while forming extrachromosomal circularized episomes in the latency phases. EBV remodels its gene expression during the life cycle to ensure viral replication, immune evasion, and persistence into the memory B-cell pool.[9,10] It infects oropharyngeal naïve B cells via ligation of viral envelope glycoproteins gp350 and gp42, gH and gL complex to CD21/CD3d, and MHC class II coreceptor, respectively, on B cells.[6,7,11] Upon infection, the virus gene-expression program is fully expressed and is referred as latency III. It encodes for six EBV nuclear antigens (EBNA1, -2, -3A, -3B, -3C, -LP), three latent membrane proteins (LMP1, LMP2A, LMP2B), and 46 viral untranslated RNAs, including two EBV-encoded small RNAs (*EBER1* and *EBER2*) and 44 viral microRNAs (e.g., BART and BHRF1).[7] This "growth program" drives activation, proliferation, and resistance to

cell death of infected cells. However, it is also highly immunogenic, triggering a strong cytotoxic T-cell response with clearing of most infected B cells. The surviving ones may enter the germinal-center reaction. Here, the virus restricts its gene repertoire to latency II characterized by expression of EBNA1, LMP proteins and a subset of viral noncoding RNA including EBERs. This “default program” mediates survival of infected B cells in the germinal center, their differentiation and which exit as memory B cells. To achieve viral persistence into the long-lived memory B-cell pool and avoid immune recognition, all viral antigens are silenced (latency 0). As an alternative route, EBV may directly reach resting memory B cells, bypassing the germinal center.[7,12] During homeostatic proliferation, infected memory B cells may transiently express EBNA1 (latency I), which anchors the viral episome to chromosomal DNA, passing the infection to daughter cells. Activation of memory B cells with latency 0 or I in oropharyngeal mucosa may lead to differentiation into plasma cells with the switch to the EBV lytic cycle (i.e., *BZLF1, BRLF1*), virus replication and production of new virions.[8] In this site, CD4+ and CD8+ T cells specific to EBV lytic cell proteins effectively control virus periodic reactivation.

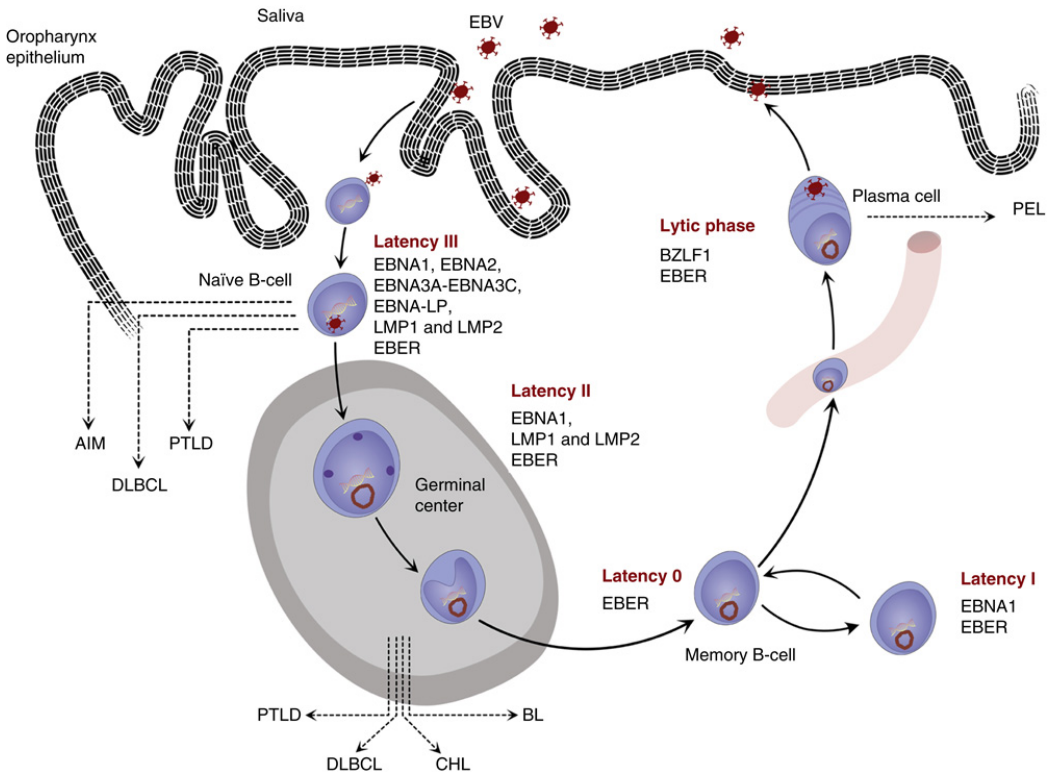

FIGURE 28-1 Model of Epstein-Barr virus infection and persistence. Epstein-Barr virus (EBV) is orally transmitted via saliva exchange. It infects naïve B lymphocytes of oropharyngeal submucosal lymphoid tissue. It forms extrachromosomal circularized episomes in the latency phases. Upon infection, the EBV enters latency III, in which all latency genes, EBV-encoded RNAs (EBERs), and viral microRNAs are expressed. This "growth program," despite being highly immunogenic, contributes to activation, proliferation, and resistance to cell death of infected cells that may enter into the germinal center reaction. Here, the virus restricts its gene expression to latency II, in which EBNA1,

LMP1, LMP2, and EBERs are expressed. This "default program" mediates survival and differentiation. EBV-positive B cells exit the germinal center as EBV-infected memory B cells, where all viral antigens except EBERs are silenced (latency 0). These cells may transiently express EBNA1 (latency I) during homeostatic proliferation. Circulating memory B cells with latency 0 or I may home back to oropharyngeal mucosa. Their activation leads to plasma cell differentiation and the EBV switch to lytic cycle (i.e., *BZLF1*), with virus replication and production of new virions that shed into saliva, allowing virus transmission. An EBV latency type III is found in acute infectious mononucleosis (AIM), in a small subset of EBV-positive diffuse large B-cell lymphoma (DLBCL), and EBV-lymphoproliferative disorders in immunosuppressed individuals, such as posttransplant (PTLD). The germinal center differentiation pathway of EBV-infected B cells likely provides precursors of most EBV-associated DLBCL, PTLD, classic Hodgkin lymphoma (CHL), and Burkitt lymphoma (BL). Although derived from the germinal-center B cells, BL manifests an EBV latency I. As a reflection of plasmacytic differentiation, an

increased lytic EBV replication can be found in primary effusion lymphoma (PEL).

EBV Transformation and Oncogenesis

EBV is an oncogenic virus, considered a class I carcinogen by the World Health Organization (WHO)[13] with capacity to transform human B cells into indefinitely growing lymphoblastoid cell lines in culture.[14] Its pathogenicity relies on coordinated expression of latency genes, early lytic proteins, and viral noncoding RNAs. EBV-encoded genes hijack important cellular signaling pathways of cellular proliferation (LMP1 and EBNA2) and apoptosis (LMP1, LMP2, EBNA3A, EBNA3C, EBERs, lytic genes [BHRF1 and BALF1-BCL2 viral homologues]). They may induce genetic instability (EBNA1, lytic genes), deregulate the epigenome (EBNA1, EBNA2, LMP1, EBERs), and interfere with immune control (lytic genes *[BZLF1, BILF1]*, microRNAs [miRNA; BHRF1, BART], and viral cytokines [IL10, CCL5]).[6,7,15,16] LMP1 is a major oncogene. It mimics CD4-positive T-cell help in the germinal center, serving as surrogate ligand for the CD40 receptor on B cells with downstream activation of NF-κB, PI3K/AKT, MAPK, and JAK-STAT signaling pathways.[17] LMP2 simulates antigen engagement on B-cell receptors (BCRs), proving a strong survival signal and rescue from apoptosis of infected B cells.[18] EBNA2 induces the transcription of the cellular oncogene *MYC* and imitates a constitutively activated NOTCH receptor.[19] Furthermore, lytic EBV antigens and viral miRNAs contribute to an immune evasive tumor microenvironment. Early lytic EBV replication allows for high levels of IL10 and CCL5 production, with suppression of cytotoxic T-cell response and

recruitment of immunosuppressive myeloid cells, respectively.[7] EBV miRNAs promote immune escape at multiple levels. They control EBV latency programs allowing for virus persistence, downregulate MHC-restricted antigen presentation, interfere with CD8-positive T-cell recruitment, alter type I IFN response, and blunt immune sensing via Toll-like receptors.[20,21] Moreover, EBV-infected B cells involved in the germinal-center differentiation are exposed to activation-induced deaminase (AID) machinery with acquisition of additional mutations or chromosomal translocations.[22]

Despite EBV's high tumorigenicity, the finely tuned balance between pathogen and host allows most individuals to carry the virus as a persistent, silent infection. Thus primary infection is usually asymptomatic in children. It may lead to acute infectious mononucleosis (AIM) in 35% to 70% of infected adolescents/young adults in developed countries.[23,24] AIM is a self-limited condition characterized by a complex of symptoms mostly generated by the hyperactive T-cell response to control viral replication and proliferation of infected EBV B cells. Most cases resolve without sequelae within a few weeks, but some patients have a more protracted clinical course.

In cases of host immune impairments, EBV reactivation occurs and, left unchecked, may lead to autoimmune diseases (i.e., multiple sclerosis) or malignancies.[25-27] Defective immune surveillance may be linked to either primary immune defects or secondary to infection (HIV, *Plasmodium falciparum*), immunomodulatory drug use (transplant settings, autoimmune diseases), or related to age. In addition, environmental exposure and hormonal and genetic factors related to racial/ethnic variation are important players to alter and

increase susceptibility to develop EBV-related diseases. Hence, EBV contributes to 1% to 2% of human malignancies, with epithelial cancers (nasopharyngeal and gastric carcinomas) outnumbering lymphoproliferative disorders/lymphomas.[28]

EBV+ B-lymphoproliferations have a worldwide distribution and their clinicobiological characteristics are heterogeneous, ranging from benign proliferative lesions to aggressive lymphomas. Their latency pattern is also diverse and depends at least partly on the B-cell differentiation stage from which they arise. An EBV latency III is found not only in naïve infected B cells of healthy carriers and most tonsillar B cells in AIM, but also in severe immunosuppressed patients with posttransplant lymphoproliferative disorders (PTLD). Classic Hodgkin lymphoma (CHL) and most EBV-positive large B-cell lymphomas will manifest an EBV latency II and Burkitt lymphomas show a latency I (**Fig. 28-1**). Given EBERs constant and high expression in all latency phases, in situ hybridization using EBERs probes represents the gold standard and the most sensitive approach to detect EBV-infected cells in tissue specimens.

Our enhanced understanding of the EBV life cycle, its mechanisms of cellular transformation, and immune control provide opportunities for early diagnostic tool development (i.e., detection of EBV miRNAs) and novel therapeutic interventions. Prophylactic or therapeutic EBV vaccines, adoptive transfer of EBV-specific T cells, immune checkpoint inhibitors, cytolytic virus activation therapy, or poly (ADP-ribose) polymerase 1 (PARP1) inhibitors are among the promising strategies to control EBV pathologies.[29-33]

Epstein-Barr Virus–Positive Mucocutaneous Ulcer

Definition of the Disease

EBV-positive mucocutaneous ulcer (EBVMCU) is a self-limited LPD that usually presents as a solitary, painful, well-circumscribed mucosal or cutaneous ulcer, in the absence of systemic symptoms or lymphadenopathy. In patients with two or more skin lesions, the term *EBV-positive B-cell polymorphic LPD* is preferred, or when the infiltrate is more extensive beyond the ulcer bed, *EBV-positive diffuse large B-cell lymphoma, not otherwise specified (DLBCL, NOS)* or other more specific type of EBV-positive lymphoma or LPD should be considered.[34,35]

Synonyms and Related Terms

None.

Epidemiology and Clinical Features

EBVMCU often affects elderly patients with immune senescence or immunocompromised individuals in settings of organ transplantation, or iatrogenic immunosuppression (e.g., methotrexate, azathioprine, and cyclosporine), HIV infection, or inborn immune disorders. The median age of patients thus affected is 71 (range 0.5–101), with a slight female predominance. It mainly involves the oropharyngeal mucosa (70%, including tonsils), skin, and gastrointestinal tract. The latter are usually associated with iatrogenic immunosuppression.[34] In EBVMCU, a solitary lesion is often encountered, although multifocal ulcers restricted to a single anatomic site have been described.[35,36] It follows an indolent clinical course with a high rate of remission either after reduction/withdrawal of immunosuppression or spontaneously, and rarely recurs.[35-42]

Pathology

Histologically, the mucosal or cutaneous ulcer is shallow or deep and often sharply demarcated by a rim of small lymphocytes (**Fig. 28-2**). The ulcer bed consists of a polymorphous infiltrate with scattered or clustered large, atypical cells, often with immunoblastic and Hodgkin and Reed-Sternberg (HRS)–like features. Variable numbers of eosinophils, plasma cells, histiocytes, and small lymphocytes are admixed. Based on the density and cytologic features of the atypical lymphocytes, four morphologic patterns have been described: polymorphous, large cell-rich (DLBCL-like), CHL-like, and mucosa-associated lymphoid tissue lymphoma-like (MALT-like). Angioinvasion and focal necrosis are often seen. The adjacent epithelium may be hyperplastic or show reactive atypia.

Phenotypically, the large atypical lymphoid cells are variably positive for B-cell markers (CD20, CD79a, PAX5, OCT2) and BCL6, and commonly express IRF4/MUM1 and CD30, with CD15 staining observed in up to half of cases.[36,38,39,41] They typically show EBV latency type II or III and EBER highlights the wide size range of the atypical B cells. A large number of small T cells delimit the ulcer bed, contributing to its sharp demarcation. Less than 50% of EBVMCU cases show a clonal immunoglobulin gene rearrangement and up to 30% may also demonstrate a clonal T-receptor gene rearrangement.[35,36,39] So far, no recurrent gene mutations have been identified.[43]

Distinction of EBVMCU from EBV-positive DLBCL, NOS usually requires an excisional biopsy and meticulous clinical assessment. In contrast to EBV-positive DLBCL, NOS, the EBV viral load, soluble interleukin 2 receptor (sIL-2R), and LDH are not increased in most

patients with EBVMCU, supporting its localized nature.[35,36,38] Decreased immune surveillance by cytotoxic T cells with impaired function or restricted repertoire and further exposure to a site-specific trigger (i.e., tooth extraction) are likely involved in EBV-positive B-cell expansion in EBVMCU.[36,39]

Epstein-Barr Virus–Positive Diffuse Large B-Cell Lymphoma, NOS

Definition of the Disease

EBV-positive DLBCL, NOS is a B-cell malignancy in which most atypical cells (>80%) are EBV infected. By definition, no case of EBV-positive B-cell lymphoma with known underlying primary or acquired immune deficiency/dysregulation should be classified in this category. Furthermore, other well-defined EBV-associated disorders (e.g., Burkitt lymphoma, lymphomatoid granulomatosis [LyG], CHL, primary effusion lymphoma, plasmablastic lymphoma, or DLBCL associated with chronic inflammation) should be excluded.

It was originally described as *senile EBV-associated B-cell lymphoproliferative disorder* or *EBV-positive DLBCL of the elderly* given its occurrence in patients older than 50 years without any known immunodeficiency or prior lymphoma.[44] Its pathobiology was attributed to immunesenescence inherent to physiologic aging. In the original description by Oyama and colleagues, EBV-positive LPD in the elderly showed striking similarities with PTLDs, frequent extranodal presentation, and an overall survival inferior to the EBV-negative DLBCL.[45,46] However, subsequent studies have shown that EBV-positive DLBCL was not restricted to the elderly and also

occurred in younger patients, in the absence of an underlying immune impairment.[47-56] To reflect these observations, it is now designated as *EBV-positive diffuse large B-cell lymphoma, NOS*.[34,57]

Synonyms and Related Terms

WHO revised 4th ed.: EBV-positive DLBCL, NOS
WHO proposed 5th ed.: EBV-positive DLBCL

In the ICC and revised WHO 4th ed., NOS was added to indicate that it did not fit any of the other more specific types of EBV-positive large B-cell lymphoma.

Epidemiology

The precise incidence of EBV-positive DLBCL is unknown, as no large population-based studies have been performed to date and it is likely underestimated, as EBV testing is not routinely performed. Based on case series, it accounts for 2% to 5% of all DLBCLs in Western countries[47,48,51,56,58-60] with a higher prevalence (9%–28%) in Asia and Latin America.[46,48,53,61-66] Its incidence increases with age, with a peak in the seventh and eight decades of life, and a smaller peak observed in the third decade of life.[56,67] Among younger patients (<50 years), EBV positivity in DLBCL ranges from 6.7% to 8%.[51,52,54] Males are more commonly affected than women (male-to-female ratio of 1.5–3.6:1).

Clinical Features

Patients commonly present with B-symptoms and nodal disease. Extranodal involvement is frequently observed in the elderly (50%–

70%)[37,45,53,56,62,68] and occasionally found in younger individuals.[54,55] The extranodal sites include skin, lung, gastrointestinal tract, and bone marrow. Thus the symptoms are variable. A subset of patients develops hemophagocytic lymphohistiocytosis (HLH).[56] EBV DNA is detectable in the serum or blood of most patients and the viral load seems to correlate with disease burden.[69] Based on retrospective studies, the clinical outcome of elderly patients is poor, with a median overall survival of 24 to 36 months.[46,62] The prognostic effect of EBV status remains controversial in DLBCL treated with immunochemotherapy.[37,53,56,59,60,63,70-75] The response to therapy of younger patients is significantly higher, and most achieve long-term survival.[51,52,54]

Pathology

EBV-positive DLBCL shows a broad histologic spectrum, with geographic necrosis and angiocentric/angiodestructive lesions frequently observed. The lymph node or the extranodal site show architectural effacement by an abnormal lymphoid infiltrate comprising large cells resembling centroblasts, immunoblasts, HRS-like cells, lymphocyte predominant (LP)-like cells, and occasional highly pleomorphic cells. Several morphologic variants are recognized based on the density and amount/type of inflammatory background and cytologic appearance of the neoplastic cells.[37,46,56,68,70,76] Most commonly, EBV-positive DLBCL is characterized by a variable number of large cells in a background rich in small lymphocytes, histiocytes, plasma cells, and occasional eosinophils. This histologic pattern, originally referred to as the

polymorphic subtype by Oyama et al.,[61] may resemble T-cell/histiocyte–rich large B-cell lymphoma (**Fig. 28-3**) or CHL (**Fig. 28-4**). Other cases show a monomorphic appearance with sheets of large cells indistinguishable from EBV-negative DLBCL, NOS (**Fig. 28-5**). Rarely, the full spectrum of B-cell maturation stages with plasmacytoid differentiation and abundant immunoblasts resembling a polymorphic posttransplant lymphoproliferative disorder is encountered (**Fig. 28-6**). These morphologic patterns do not seem to have prognostic significance.[37,56,70]

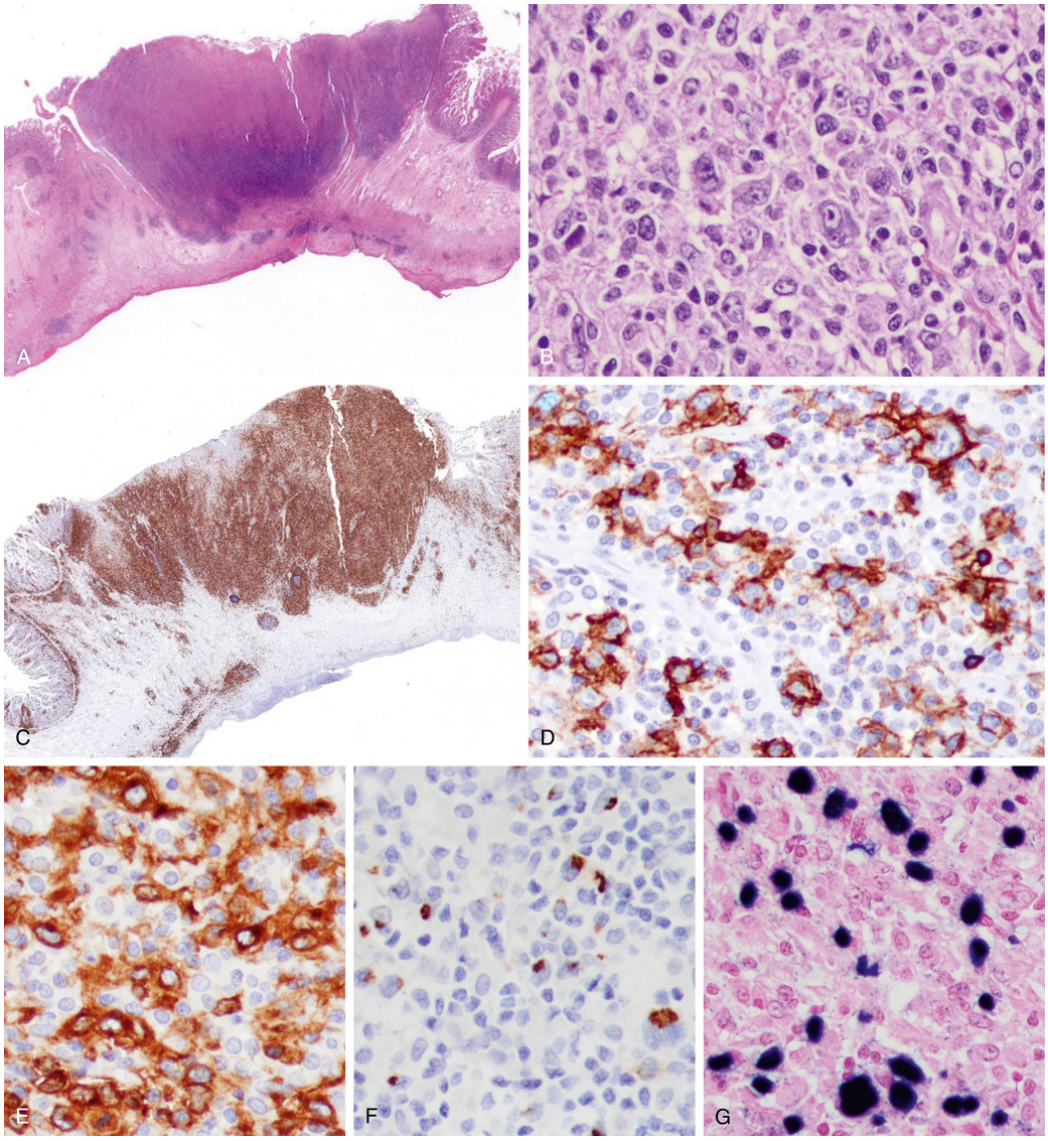

FIGURE 28-2 Epstein-Barr virus–positive mucocutaneous ulcer.A, Isolated, well-circumscribed small bowel ulcer. **B,** The lesion consists of a polymorphous infiltrate with scattered large, atypical cells, sometimes with Reed-Sternberg–like features in a rich histiocytic background. **C,** The ulcer bed is sharply demarcated by small, CD3-positive T-lymphocytes. **D,** The atypical cells strongly

express CD20 and CD30 **(E)** and are focally positive for CD15 with a dot-like pattern **(F)**. **G,** EBV-encoded RNA (EBER) highlights a range of cell sizes, including the large pleomorphic lymphocytes.

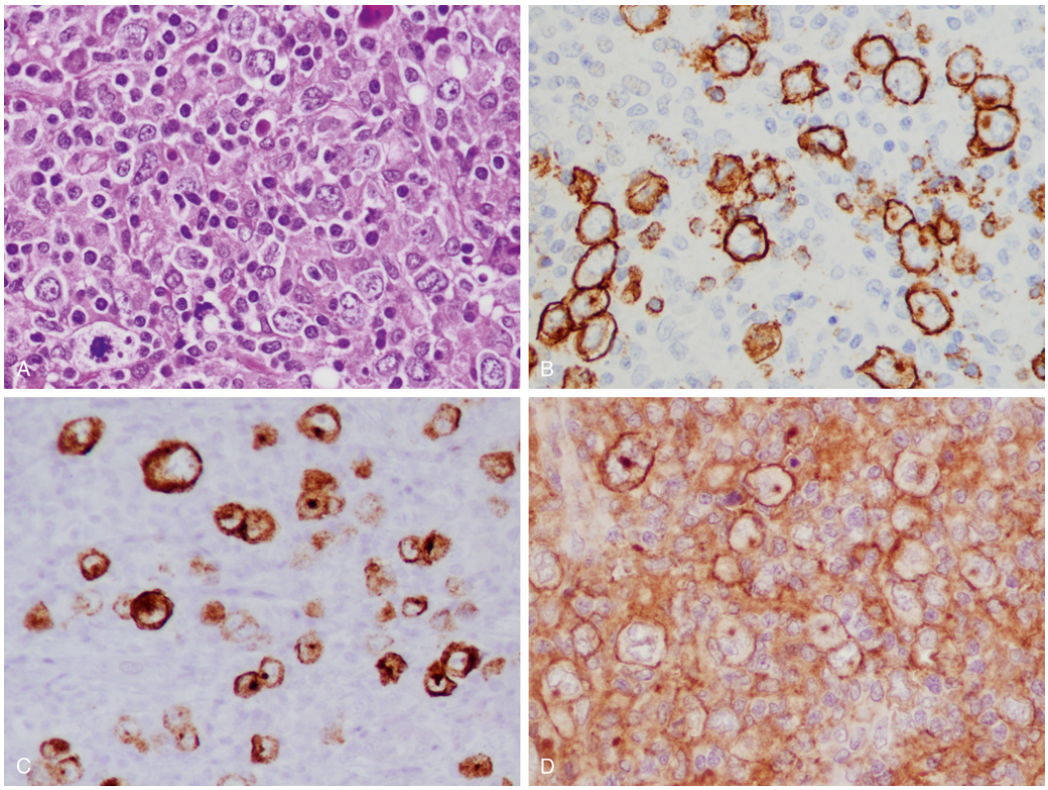

FIGURE 28-3 Epstein-Barr virus–positive diffuse large B-cell lymphoma, not otherwise specified resembling T-cell/histiocyte–rich large B-cell lymphoma.A, Scattered large, atypical cells with vesicular nuclei are seen in a background rich in histiocytes and small lymphocytes. **B,** The atypical cells are strongly CD20 positive and no small B cells are noted in the background. They also express LMP1 **(C)** and PD-L1 **(D)**.

Immunophenotypically, the large cells usually express pan–B-cell markers and even in the absence of CD20 expression, they still conserve a strong B-cell program (positivity for CD19, CD79a, PAX5, OCT2, and BOB-1) (**Figs. 28-3 to 28-6**). They often have a post–

germinal-center/activated B-cell phenotype with IRF4/MUM-1 positivity, and variable expression of CD10. Most cases show focal or diffuse staining for CD30 with CD15 expression observed in a small subset.[37,53,54,56,59,68,70,75] The neoplastic cells frequently express PD-L1 and PD-L2.[54,56,74,77,78] By definition, the atypical cells are EBV positive using in situ hybridization, with EBER demonstrated in the majority of tumor cells (>80%). The low cutoffs (between 10% and 20%) of EBV-positive B cells used in several studies raise doubts about the pathogenic role of EBV in such instances.[47,48,62] LMP-1 is expressed in most cases (>90%), with EBNA-2 detected in up to one-third of patients (7%–36%), consistent with a predominant EBV latency type II.[46,54,56,59]

EBV-positive DLBCL showing HRS–like cells in a reactive inflammatory background is particularly challenging to distinguish from mixed cellularity CHL. In contrast to CHL, EBV-positive DLBCL may involve extranodal sites, show a preserved B-cell program, and lack CD15 in most cases.[37,46] In addition, EBER highlights a wider variation in nuclear size of atypical cells in comparison to CHL, where the positivity is more restricted to the HRS cells. In extranodal sites, the differential diagnosis includes EBVMCU and LyG. Notably, EBV-positive DLBCL shows overlapping pathologic features with other EBV-driven LPD in immune dysregulation settings. This distinction can only be made based on clinical context.

Genetics and Pathogenesis

Clonal immunoglobulin gene rearrangement is often demonstrated (60%).[37,54,70] Approximately half of tested cases show a “restricted”

or oligoclonal T-cell receptor gene rearrangement, as reflection of reduced T-cell repertoire (senescence) or expanded EBV-specific CD8 cytotoxic T cells.[37]

The pathogenesis of EBV-positive DLBCL is complex and not fully elucidated. It involves disruption of the finely tuned balance between latently EBV-infected B cells and the host immune system, as well as genomic alterations intrinsic to the neoplastic cells. The immunosenescence or the physiologic decay of the immune system with aging is thought to underlie the biology of this neoplasm in elderly patients (>70 years). Both innate and acquired immunity are remodeled with age, although changes in the T-cell compartment reflect the reduced generation of lymphoid precursors, thymic atrophy with diminished output of naïve T cells, restricted T-cell receptor repertoire, anergic memory cells, and accumulation of viral-specific CD8 T cells, often CMV specific.[79,80] These changes in the T-cell compartment allow latently EBV-infected B cells to expand. The oncogenic driver mechanisms elicited by EBV products exceed other genomic events, explaining the low mutational burden and scarce recurrent abnormalities observed in EBV-positive DLBCL.[78,81] However, they display a broad intratumor heterogeneity with different subclonal populations.[82] Among the genes involved, there is a significant enrichment in alterations in NF-κB, WNT, and IL6/JAK/STAT pathways, as well as in epigenetic modifiers.[81,83,84] An enhanced activity of these pathways and of genes involved in Toll-like receptor signaling and antiviral response have been documented by gene-expression profile studies.[59,78,85] Of note, *CCR6, DAPK1, TNFRSF21,* and *CCR7* mutations, observed in approximately 15% of cases, appear to be specific for EBV-positive

DLBCL. In addition, 6q deletion that encompasses *PRDM1* and *A20/TNFAIP3* is a recurrent feature (44%) of this neoplasm.[81] Interestingly, a mutual exclusivity has been observed between EBV positivity and *MYD88/CD79B* mutations and *MYC, BCL2,* and *BCL6* rearrangements in DLBCL.[86]

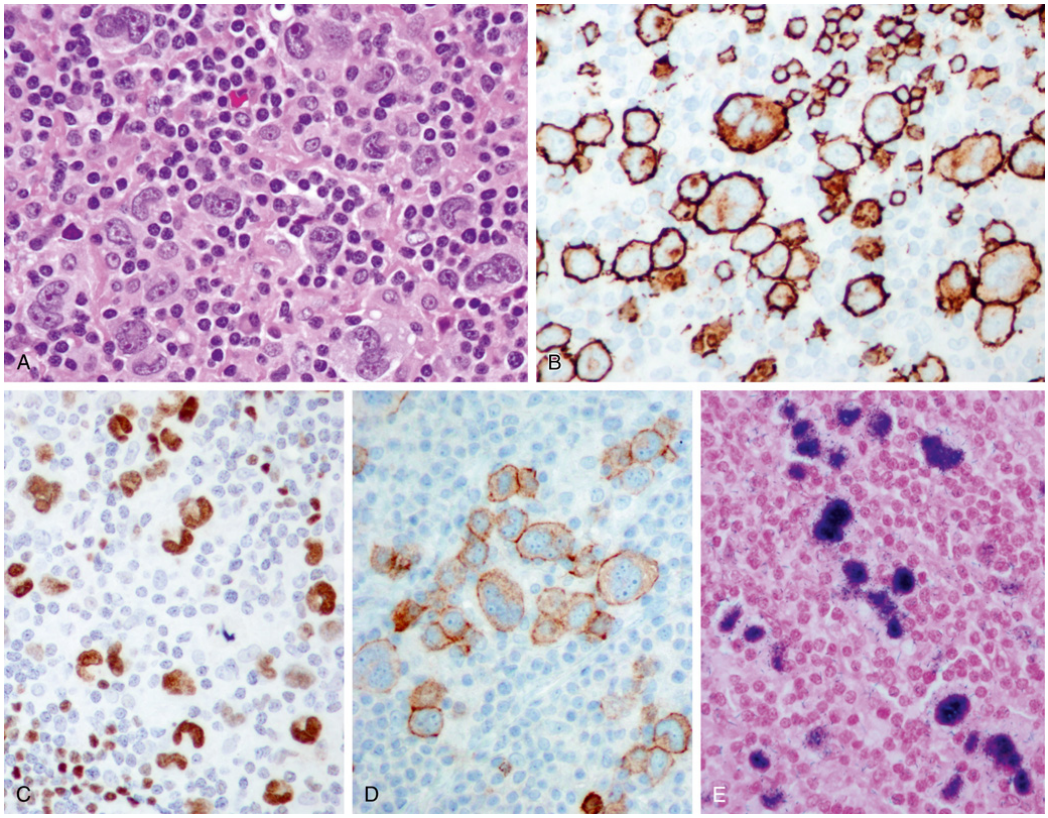

FIGURE 28-4 Epstein-Barr virus–positive diffuse large B-cell lymphoma, not otherwise specified resembling classic Hodgkin lymphoma.A, Large, atypical cells with Reed-Sternberg–like features are noted in a background rich in histiocytes and small lymphocytes. These cells are strongly and uniformly positive for CD20 **(B)** and OCT2 **(C)**. They also express CD30 **(D)** and Epstein-Barr virus (EBV)-encoded RNA **(E)**. Note the range in size of atypical EBV-infected lymphocytes.

Immune tolerance of EBV-infected B cells is another crucial mechanism involved in the pathobiology of this neoplasm, mainly in younger patients.[54,87] The neoplastic EBV-positive B cells

overexpress immune checkpoint ligands PD-L1 and PD-L2. The mechanisms involved are multifactorial and related to EBV proteins and cytokine milieu (IFN-γ). EBV-LMP1 upregulates PD-L1/L2 through JAK/STAT, AP-1, and NF-κB pathways and this is finely regulated by EBV miR-BHRF1-2-5p.[70,88,89] In addition, EBNA2 downregulates miR-34a and alters PD-L1 expression in cases with EBV latency type III.[90] Furthermore, genetic abnormalities at the 9p24.1 *(PDL1/PDL2)* locus have been detected in 19% of cases.[78,83] Altogether, this makes EBV-positive DLBCL an attractive target for PD-1/PD-L1/PD-L2 inhibitors.[74,91]

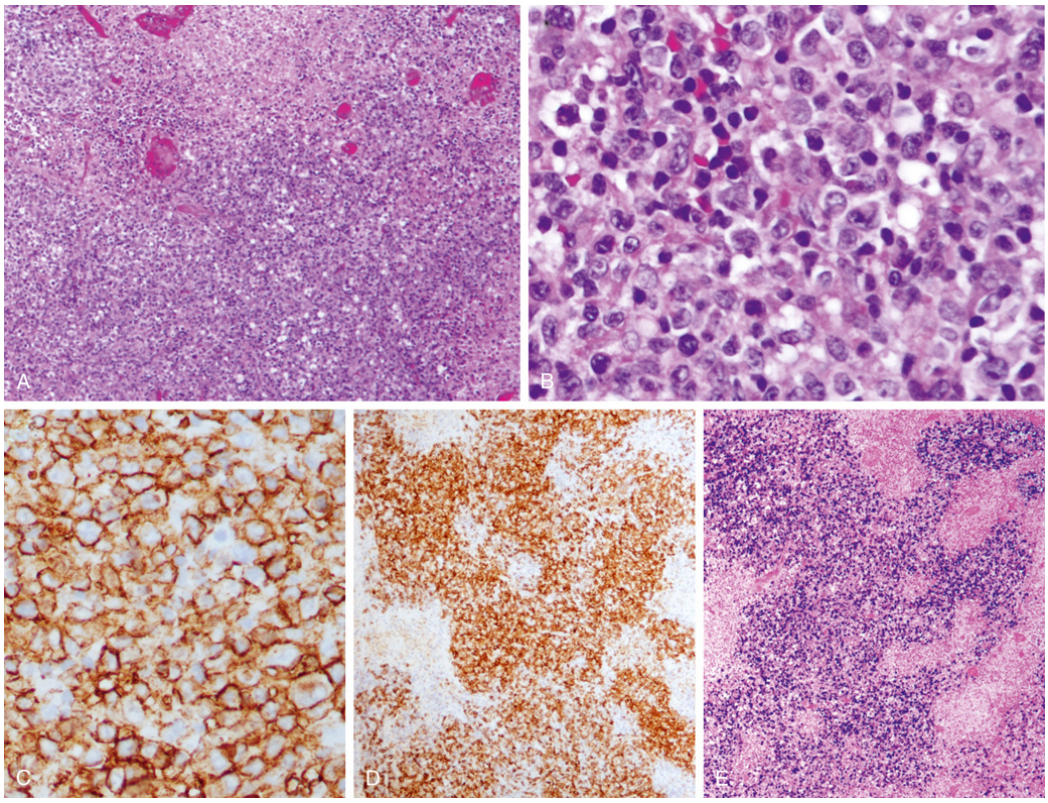

FIGURE 28-5 Epstein-Barr virus (EBV)-positive diffuse large B-cell lymphoma, not otherwise specified indistinguishable from EBV negative diffuse large B-cell lymphoma, not otherwise specified.A and **B,** Sheets of large atypical lymphoid cells with extensive areas of necrosis. The large cells are strongly and uniformly positive for CD20 **(C)**, CD30 **(D)**, and EBV by in situ hybridization **(E)**.

Diffuse Large B-Cell Lymphoma Associated With Chronic Inflammation

Definition of the Disease

DLBCL associated with chronic inflammation (DLBCL-CI) is a rare form of EBV-positive lymphoma that occurs in context of long-standing chronic inflammation. Originally called pyothorax-associated lymphoma (PAL), it is characterized by a mass-forming lesion, usually involving the pleural cavity.

Synonyms and Related Terms

Pyothorax-associated lymphoma (subset).

Epidemiology and Clinical Features

Most cases are reported in patients with chronic pyothorax after pleurodesis used to treat pulmonary tuberculosis.[92-95] It is more common in Japan, where therapeutical pneumothorax was a popular practice, and rare in Western populations. Cases subsequent to chronic empyema after trauma or pneumonectomy have also been described. The mean latency time from infection to lymphoma development was 37 years (range 20–60 years).[92,93,95] DLBCL-CI may rarely occur decades after chronic osteomyelitis and venous skin ulcers or it may arise subsequent to metallic joint prosthesis and surgical mesh implants.[39,96-98] Patients with PAL are commonly in their 70s and there is a marked male predominance (male-to-female ratio >9:1).[92,95,99]

Most patients with PAL are immunocompetent and have a long history of chronic pyothorax. They often present with back or chest pain, fever, cough, dyspnea, or chest tumor mass. The imaging studies usually reveal a large (>10 cm) lenticular or crescent-shaped mass at the margin of the empyema cavity, often at the lateral costal pleura or costophrenic angle.[100] Despite the localized stage of

disease at presentation, the outcome of PAL is poor, with an overall survival rate at 5 years of 20% to 35%.[92,95]

Pathology

Typically, there is a diffuse proliferation of large lymphoid cells involving pleura and adjacent structures. The atypical cells show immunoblastic, centroblastic, or less frequent plasmablastic features (**Fig. 28-7**).[92,93,95] Necrosis and angiocentricity are commonly seen, as well as various degrees of fibrosis and chronic inflammation. By immunohistochemistry, the neoplastic cells express CD45 and usually pan–B-cell markers. They are frequently positive for IRF4/MUM1 and CD43 (75%), while lacking CD10 and BCL6, in keeping with a post–germinal-center phenotype.[93] The neoplastic cells may stain for CD30 and show aberrant expression of T-cell markers (CD2, CD3, or CD4).[92,93] They manifest an EBV latency type III (positivity for EBER, LMP1, and EBNA2) and are HHV-8 negative.

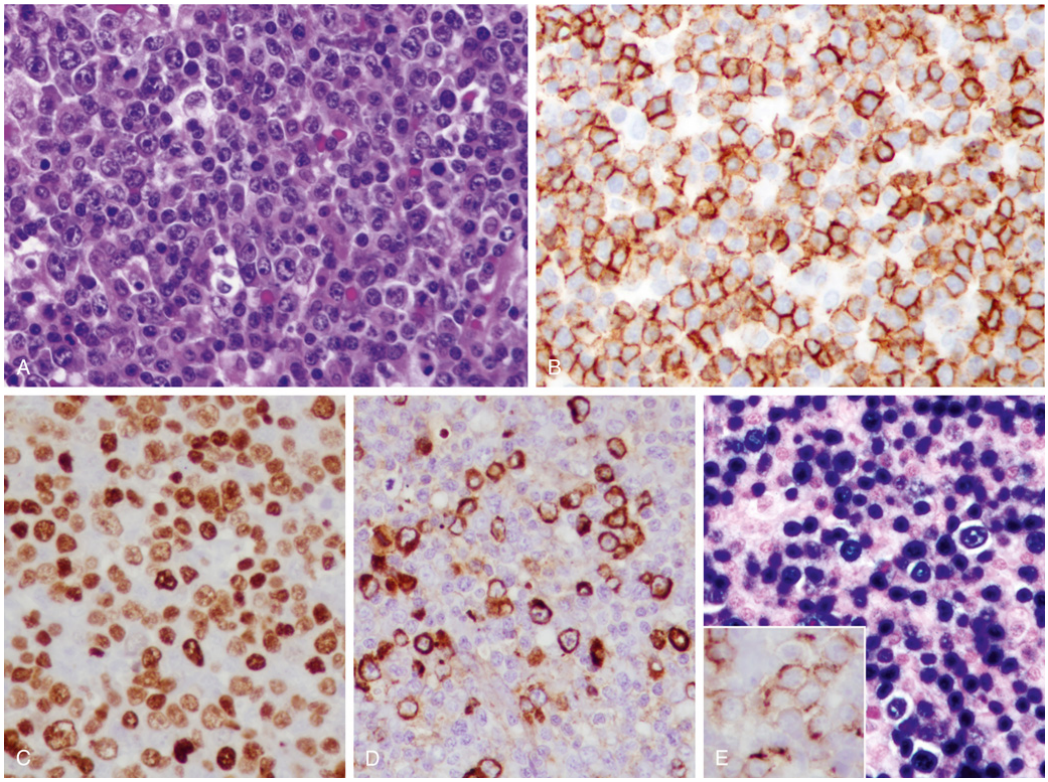

FIGURE 28-6 Epstein-Barr virus–positive diffuse large B-cell lymphoma, not otherwise specified resembling a polymorphic posttransplant lymphoproliferative disorder.A, The neoplastic infiltrate consists of a polymorphic atypical lymphoid proliferation with plasmacytic differentiation. **B,** The atypical cells are variably positive for CD20, and show diffuse expression of IRF4/MUM1 **(C)** and IgA heavy chain restriction **(D)**. Epstein-Barr virus (EBV) is present in more than 90% of atypical cells by in situ hybridization with EBV-encoded RNA probe **(E)**, whereas a subset of cells is positive for LMP1 *(inset)*.

Pathogenesis and Genetics

DLBCL-CI is consistently EBV positive.[92,93,101,102] The putative cell of origin is considered a crippled B-cell that has passed through the germinal-center reaction.[103] Local chronic inflammation via cytokines (IL6, IL10), chemokines (CCL17, CCL22), and reactive oxygen species likely contributes to the tolerogenic microenvironment, proliferation, and slow progression of EBV-transformed B cells that escaped the host immune surveillance in the enclosed space.[39,94,101,104] There is no association with HHV-8 in contrast to primary effusion lymphoma.[93]

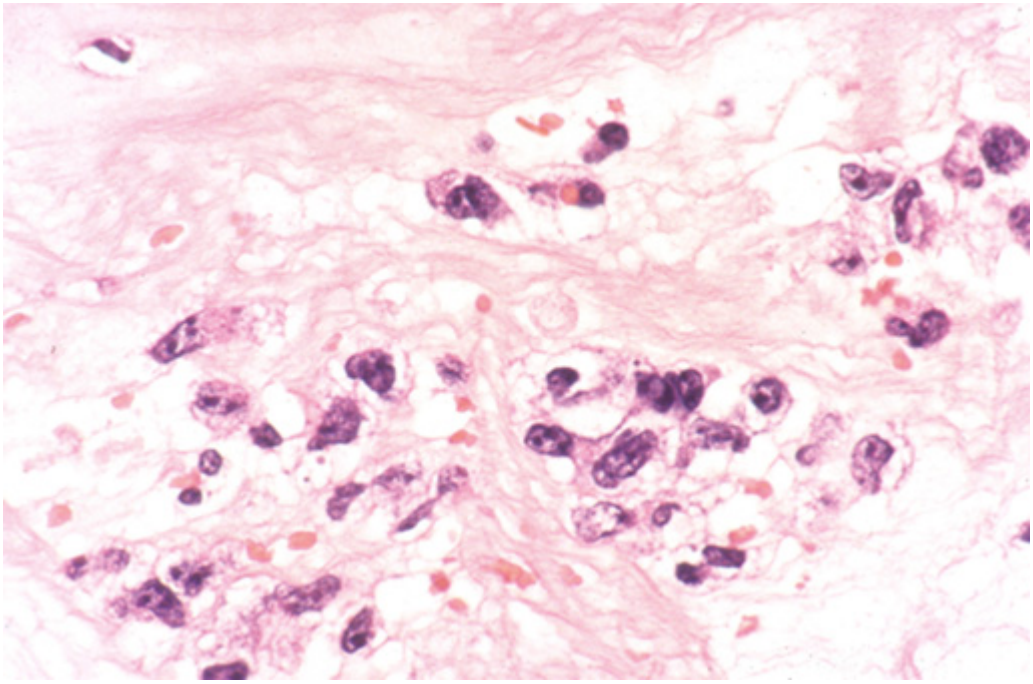

FIGURE 28-7 Pyothorax-associated lymphoma (diffuse large B-cell lymphoma with chronic inflammation). The large, atypical cells are embedded in a sclerotic stroma and fibrin. Courtesy John K.C. Chan.

PAL shows clonal rearrangements of immunoglobulin genes without evidence of ongoing somatic mutations.[101,103] It features genomic instability.[105,106] *TP53* mutations, most commonly at dipyrimidine sites, and *MYC* amplification are detected in 70% of cases[94,107,108] and one-third show *A20 (TNFAIP3)* deletion.[109] The gene-expression profile is distinct from nodal DLBCLs and is characterized, besides an EBV-related signature, by high expression of interferon-inducible genes (i.e., *IFI27*), a feature of chronic inflammation.[110]

Fibrin-Associated Diffuse Large B-Cell Lymphoma

Definition of the Disease

Fibrin-associated DLBCL (FA-DLBCL) is rare, with only case reports and small series described so far. It is characterized by microscopic foci of neoplastic B cells admixed with fibrin exudate in confined anatomic spaces. It follows an indolent clinical course, with no mass formation or infiltrative growth pattern, as opposed to DLBCL-CI.

Synonyms and Related Terms

WHO revised 4th ed.: Fibrin-associated DLBCL
WHO proposed 5th ed.: Fibrin-associated large B-cell lymphoma

Epidemiology and Clinical Features

FA-DLBCL is often incidentally found in surgical specimens removed for various conditions that predispose to fibrin accumulation. Some patients may present with thromboembolic events. It has been seen most commonly lining the surface of cardiac myxomas (32%, frequently of left atrium), in association with prosthetic cardiac valves or endovascular grafts. It also involves pseudocysts (18%), hydrocele, chronic subdural hematoma, or relates to orthopedic devices.[111-116] FA-DLBCL has also been documented in settings of breast implants.[117-119] The time from graft/device placement to lymphoma diagnosis ranges from 1 to more than 20years. Patients are usually immunocompetent adults (median age 60, range 25–96 years) with male predominance (male-to-female ratio of 2.5:1). They show localized stage IE disease (Lugano classification),[120] with lymphoma restricted to a single extranodal site and have an excellent prognosis. Although no therapeutic guidelines are available so far,

early FA-DLBCL diagnosis, complete lesion excision, and close follow-up are likely the optimal strategy.[113,121]

Pathology

FA-DLBCL presents as microscopic aggregates of large lymphoid cells embedded within an abundant fibrinous background (**Fig. 28-8**). There is no extension to the adjacent normal tissue, although focal infiltration of cardiac myxoma or fibrous capsule may be seen. The atypical cells frequently show irregular nuclei, ≥1 conspicuous nucleoli, and moderate amount of cytoplasm, sometimes with plasmacytic differentiation. Mitotic figures and apoptotic bodies are numerous. Scattered macrophages and chronic inflammation may be associated.

Immunophenotypically, the neoplastic B lymphocytes are CD79a and PAX5 positive, variably express CD20 and CD30, and are seldomly CD138 positive. They frequently have a nongerminal-center B-cell phenotype with IRF4/MUM1 expression and a high Ki67 proliferation index (>90%). Most cases are EBV positive, notably with latency type III (expression of LMP1 and EBNA2). HHV-8 is negative. A monoclonal immunoglobulin gene rearrangement is often detected, but *MYC, BCL6,* or *BCL2* rearrangements or amplifications are usually absent by fluorescence in situ hybridization (FISH) studies.[113]

Given its rarity, FA-DLBCL pathogenesis is largely unknown with no genetic study published so far. It has been suggested that acquired local immunosuppression and restricted environment provided by the dense fibrin strands are contributing to immune evasion and malignant transformation of EBV-infected B cells.[113,122]

Lymphomatoid Granulomatosis

Definition of the Disease

LyG is a rare, progressive, angiocentric, and angiodestructive EBV-associated B-cell LPD that typically involves extranodal sites. Lung involvement is required for the diagnosis.[34,124] The infiltrate characteristically contains scattered EBV-positive B cells and a predominant T-cell background.[125-127] The term was coined by Liebow and colleagues in 1972 to distinguish it from Wegener's granulomatosis (WG), which shares similar clinical and pulmonary radiologic findings.[128]

Synonyms and Related Terms

None.

Epidemiology

LyG occurs in otherwise healthy individuals, although most of them have some degree of quantitative or qualitative impairment of cellular (CD8-positive T cells) or humoral immune response to EBV.[124,127,129] It has been sporadically described in patients with both inborn (i.e., Wiskott-Aldrich syndrome, *DOCK8* deficiency) and acquired immune deficiency (autoimmune diseases, HIV infection, or iatrogenic immunosuppression).[130-134] However, these latter cases are likely distinct from classic LyG and require designation as LPD associated with immune deficiency and dysregulation.[34] LyG presents in adulthood, between the fourth and sixth decade of life, and rarely occurs in children. The male-to-female ratio is approximately 2:1 and there is no racial predisposition.[132,133,135-138]

Clinical Features

LyG is virtually always an extranodal disease, with nearly all patients presenting with bilateral lung involvement. Other common sites include central nervous system (CNS; 40%), skin (34%), kidneys (19%), and liver (17%).[132,133,136,138] Lymph node, spleen, and bone marrow are spared at diagnosis and thus, LyG diagnosis should be questioned if lymph nodes are involved.[133] Presenting symptoms are often insidious (i.e., fever, cough, dyspnea, or chest pain) and the lung lesions may wax and wane, leading to delay in diagnosis. Pulmonary imaging usually shows multiple bilateral lung nodules, frequently in the middle and lower lobes. The nodular lesions are variable in size, usually with peribronchial and vascular distribution, and may display necrosis or cavitation (**Fig. 28-9**).[132,133,136] CNS involvement on magnetic resonance imaging may show mass lesions or multiple cortical infarcts and has been associated with a poor prognosis.[133,135,136] Though these patients may initially be asymptomatic, confusion, dementia, ataxia, hemiparesis, and seizures or cranial nerve–related signs are likely to develop over time. Cutaneous manifestations are heterogeneous and rarely precede the lung lesions. They present often as disseminated erythematous papules or subcutaneous nodules or, less frequently, as indurated plaques (**Fig. 28-10**).[124,133,135,139,140] Patients show evidence of prior EBV exposure by serology and an often low level of viremia, in contrast to other EBV-driven lymphoproliferative disorders.[133] The clinical behavior is heterogeneous and depends on histologic grade. Although spontaneous regression can be seen, 60% of patients died of disease, with a median overall survival of 14 months.[124]

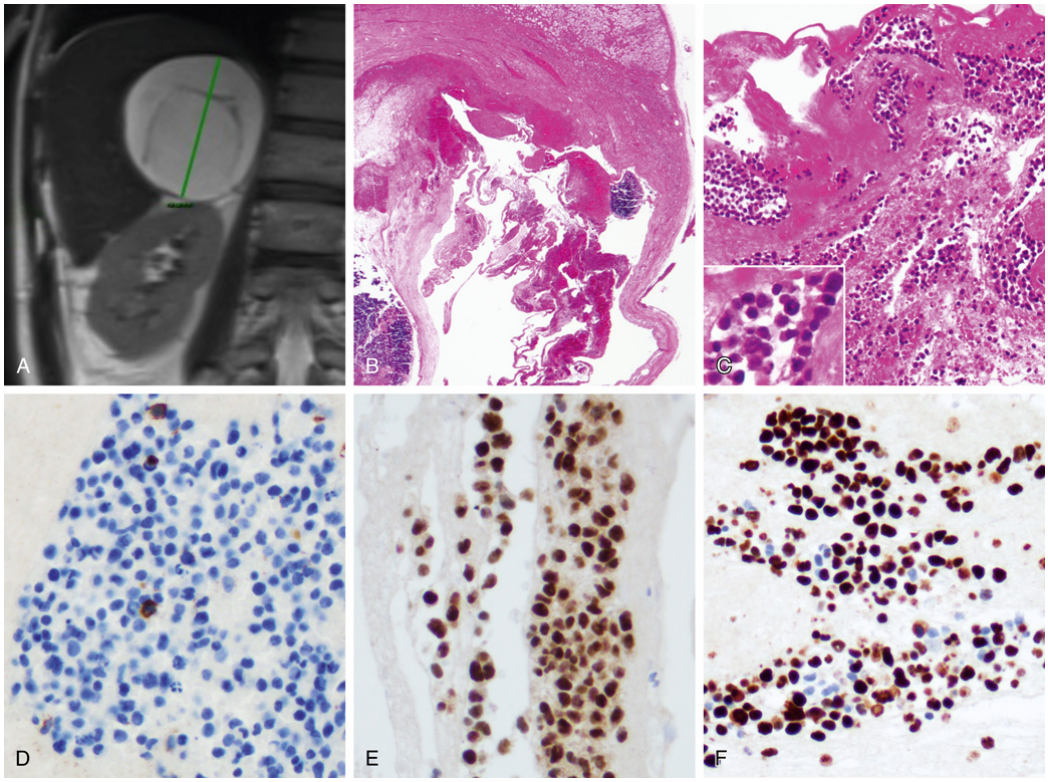

FIGURE 28-8 Fibrin-associated diffuse large B-cell lymphoma involving an adrenal cyst.A, Magnetic resonance image identified a 10-cm cyst with false membranes and no other associated lesion. **B,** Thick, hyalinized fibrous wall with no luminal lining and entrapped adrenal cortical cells. The lumen of the pseudocyst was filled with fibrin, blood, necrotic debris, and degenerative calcification. **C,** Nests of atypical medium-sized lymphocytes, with round nuclei, dense chromatin, and scant cytoplasm *(inset)* embedded in an abundant fibrinous background, with no infiltration of the fibrous wall. **D,** They were negative for CD20, but strongly expressed PAX5 **(E)**. **F,** The atypical

lymphocytes showed an EBV latency III, with expression of EBNA2.

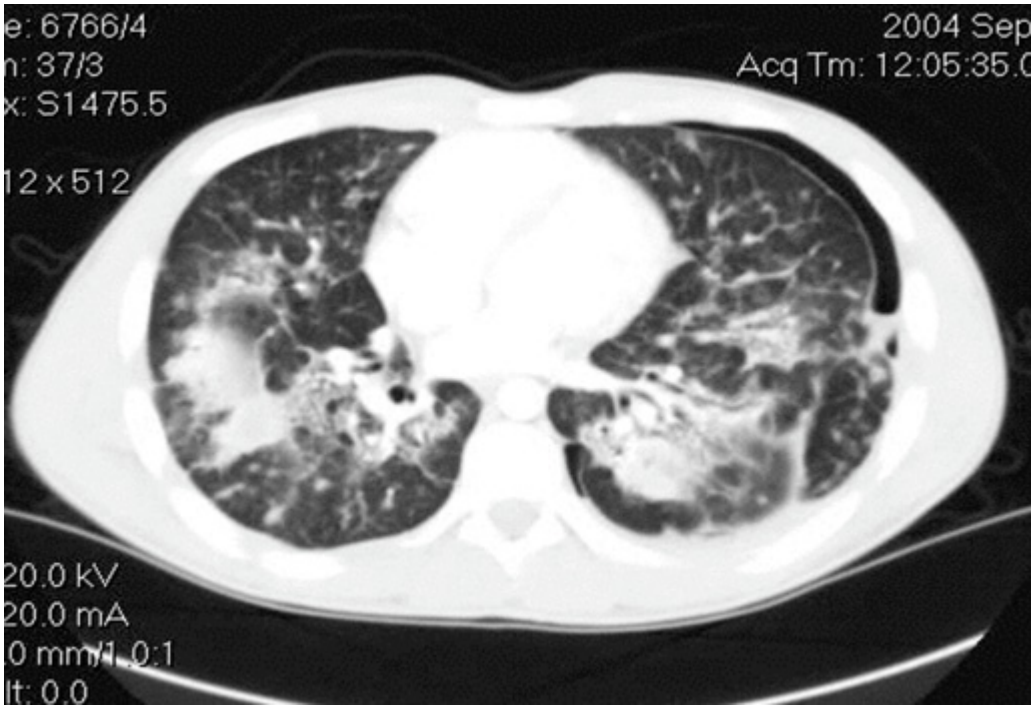

FIGURE 28-9 Lymphomatoid granulomatosis involving the lungs. Computed tomographic scan shows pulmonary nodules, sometimes with central necrosis, that are seen most often in the lower lung fields.

FIGURE 28-10 **Cutaneous manifestations of lymphomatoid granulomatosis.A,**

Papulonodular lesions are common. **B,** Larger nodules may show ulceration.

Pathology

An adequate, usually excisional biopsy is required for an accurate diagnosis and grading of LyG. The most typical histologic features are observed in the lung nodules. All lesions are angiocentric, with various degrees of angioinvasion and angiodestruction of small-to-medium caliber vessels. The infiltrate is polymorphous with admixture of small lymphocytes, histiocytes, and variable numbers of large atypical lymphoid cells. Plasma cells, when present, are not prominent; neutrophils, eosinophils, multinucleated giant cells, and well-formed granulomas are not seen. Necrosis is common and varies in extent. It is coagulative, often centered on vessels, and contains nuclear debris, but no neutrophils as opposed to necrotizing lesions of WG (**Fig. 28-11**).[141] The EBV-positive B cells, the hallmark of LyG, are medium-to-large in size, and may resemble immunoblasts and occasionally HRS cells. Similar findings are seen in the brain, kidney, and liver lesions.[140] In the skin, the subcutaneous lesions resemble a lymphohistiocytic panniculitis with or without multinucleated giant cells, granulomas, and foci of necrosis. Nonspecific plaquelike lesions with a sparse, superficial dermal periadnexal and perivascular lymphoid infiltrate reminiscent of lichen sclerosus et atrophicus can be observed in a subset of patients. EBV-positive atypical B cells are usually absent in this site.

LyG is divided in three histologic grades based on density of EBV-positive B cells.[127,142] This has prognostic and therapeutic implications, since strategies to improve the host's immune system

are usually used for grade 1 and 2 lesions, whereas chemotherapy (DLBCL-like regimens) is required for grade 3 disease.[124] Of note, the number of atypical EBV-positive B cells may vary over time and between sites. Grade 1 lesions are characterized by a polymorphous lymphohistiocytic infiltrate with <5% of large, atypical EBER-positive cells. Focal necrosis is observed in one-third of cases.[133] CD20 stain is useful to highlight the large B-cells. For cases lacking EBV-positive cells, a LyG diagnosis should be made with caution and supported by a high clinical and radiologic suspicion and dense angiocentric T-cell infiltrate. Grade 2 and 3 lesions are morphologically less challenging, as large atypical EBV-positive cells are readily identified. They are usually 5 to 50 cells/high-power field (HPF) in grade 2 and >50 cells/HPF with clusters or aggregates formation in grade 3 (**Fig. 28-12**).[133] An inflammatory background rich in T cells is always associated and necrosis is common. A uniform population of large atypical EBV-positive cells without a polymorphous inflammatory background should be classified as EBV-positive DLBCL, NOS and is beyond the spectrum of LyG as currently defined.

Phenotypically, the large atypical EBV-positive cells express pan–B-cell markers (CD20, PAX5, or CD79a), are commonly CD30 positive, and lack CD15, which helps in the distinction from CHL. The majority of small lymphocytes are CD3-positive T cells, with a predominance of regulatory CD4+ T cells over CD8+. The EBV latency is type III with expression of LMP-1, EBNA-2, and ZEBRA in most cases.[133] Clonal immunoglobulin gene rearrangement is more commonly demonstrated in grade 2 (50%) and 3 lesions (70%) than in grade 1 LyG (<10%), likely because of the paucity of EBV-positive

B cells in the latter.[133] The differential diagnosis of LyG includes other lymphomas and inflammatory and infectious disorders affecting the lung (**Box 28-1**).

Pathogenesis

LyG pathogenesis is likely the result of local defective immune surveillance by CD8+ cytotoxic T cells and abnormal immune reaction toward EBV. The vasculitic changes and tissue necrosis are related to direct invasion of vessels by inflammatory cells in response to EBV and chemokine mediated (CXCL9 and CXCL10).[124,129] Conversely, a systemic immune response toward EBV likely accounts for the cutaneous manifestations in LyG based on the paucity of EBV-positive B-cells and granuloma formation.

Epstein-Barr Virus–Positive Polymorphic B-Cell Lymphoproliferative Disorder, NOS

The use of this term should be limited to the B-cell proliferations that do not fulfill the criteria of a well-defined EBV-positive lymphoma entity and show altered tissue architecture. Most of these cases will fall between EBV reactivation (i.e., a reactive node with preserved architecture and focal EBV positive B cells) and EBV-positive DLBCL, NOS. Some of the cases previously diagnosed as chronic active EBV disease of B-cell type may also fall in this category. This term may also apply to situations when there is uncertainty about the diagnosis because of limited and poor-quality material.

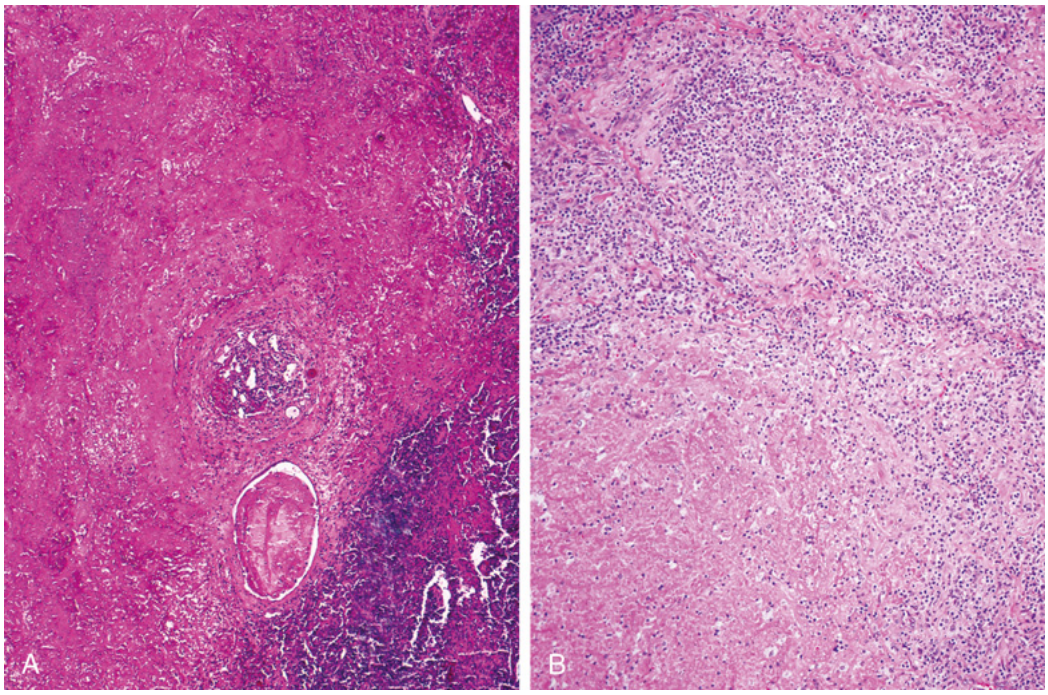

FIGURE 28-11 Vascular involvement in lymphomatoid granulomatosis.A, Necrotic nodules often contain occluded or damaged blood vessels surrounded by a dense lymphoid infiltrate. **B,** Vessels show medial and intimal infiltration by lymphocytes. Adjacent lung parenchyma is necrotic.

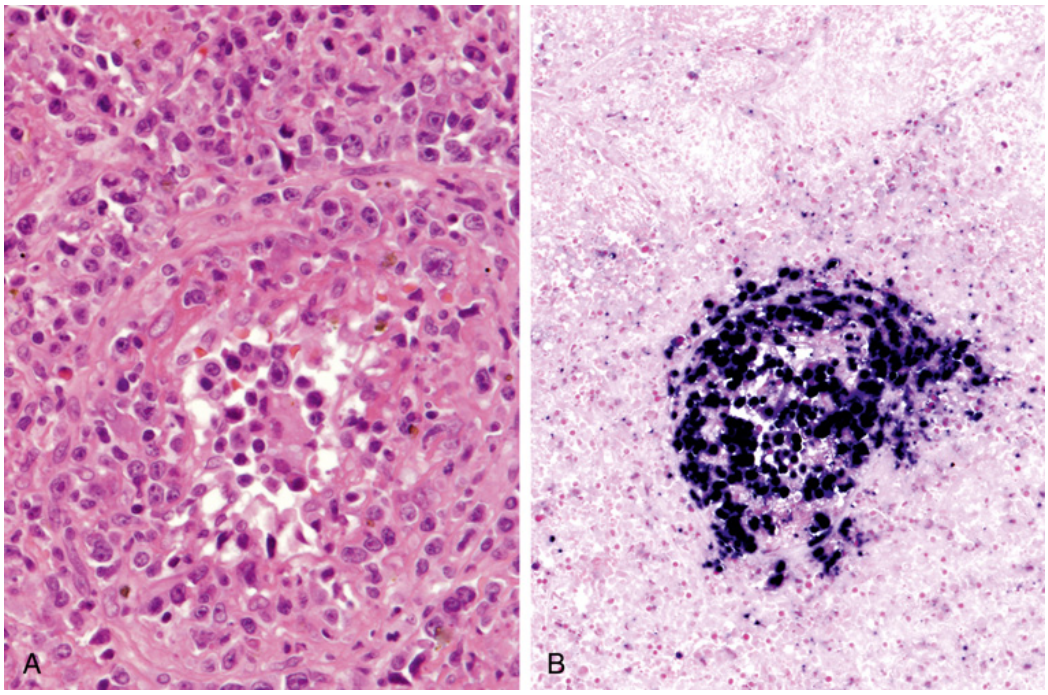

FIGURE 28-12 Grade 3 lymphomatoid granulomatosis.A, Numerous large lymphoid cells admixed with some histiocytes infiltrating the blood vessels. **B,** Epstein-Barr virus (EBV)–encoded RNA in situ hybridization from the same case. Viable atypical cells are uniformly positive for EBV. Large necrotic areas are nonreactive owing to poor RNA preservation.

Table 28-1 summarizes the key features of EBV-related B-cell lymphoproliferations including EBVMCU, EBV-positive DLBCL, NOS, DLBCL-CI, LyG, FA-DLBCL, and plasmablastic lymphoma (detailed in **Chapter 24**).

HHV-8-Associated Lymphoproliferative Disorders

HHV-8 Life Cycle and Pathogenesis

KSHV, also known as HHV-8, is endemic in sub-Saharan Africa, the Mediterranean basin, and parts of South America.[143] It was identified in 1994 in AIDS patients with Kaposi sarcoma by representational difference analysis (RDA), which allowed recognition of two DNA sequences (KS330 Bam and KS631 Bam) unique to this virus.[144,145] HHV-8 is transmitted by saliva, and mainly acquired during childhood and sexual intercourse (predominantly between men). Similar to EBV, it has latency and lytic replication phases, defined by different viral gene expression. During the latency phase, HHV-8 genome (165 kB double-stranded DNA) persists as a circular episome in the host CD19-positive B-cell nuclei.[146,147] It expresses proteins, some homologous to human, that hijack host mechanisms of viral detection and elimination, allowing for asymptomatic lifelong persistence in immune competent individuals. The lytic cycle enables virion production, with the entire HHV-8 genome transcribed. This state facilitates not only virus transmission but also its exposure to host immune detection. Both latent and lytic gene products are involved in HHV-8 pathogenesis. Latency-associated nuclear antigen (LANA/ORF73), viral cyclin (vCyclin), viral FLICE inhibitory protein (vFLIP), Kaposins (K12), viral miRNA, and viral interferon regularity factor 3 (vIRF3/LANA2) are essential for maintenance of HHV-8 latent infection, cell survival, proliferation, and angiogenesis.[148] Moreover, latently infected cells produce extracellular vesicles that shape the phenotype of adjacent uninfected cells.[149] Lytic-infected cells generate viral IL-6 (vIL-6; a homolog of human IL-6), viral G protein–coupled receptor (vGPCR), and viral interferon regulatory factor 1 (vIRF1).

These products enhance B-cell proliferation and differentiation, aberrant angiogenesis, differentiation of blood to lymphatic endothelial cells, and immune evasion.[148,150,151]

Box 28-1 Differential Diagnosis of Lymphomatoid Granulomatosis

DLBCL, Diffuse large B-cell lymphoma; *EBER,* Epstein-Barr virus–encoded RNA; *EBV,* Epstein-Barr virus; *HRS,* Hodgkin and Reed-Sternberg; *NK,* natural killer; *NOS,* not otherwise specified.

Posttransplant Lymphoproliferative Disorder

- B-cell rich rather than B-cell poor
- T-cell presence is variable
- Pattern of coagulative necrosis may be similar
- History of iatrogenic immunosuppression

Classic Hodgkin Lymphoma

- HRS cells in a background of lymphocytes, histiocytes, plasma cells, and eosinophils
- HRS cells may be EBER positive or EBER negative
- HRS cells $CD30^{+}$, $CD15^{+}$, $CD20^{-/+}$, $PAX5^{+}$, $CD79a^{-}$

DLBCL Associated With Chronic Inflammation (Pyothorax-Associated Lymphoma)

- Pleura-based lesion without primary pulmonary involvement

- EBV-positive large B cells with minimal inflammatory background
- History of tuberculosis or other cause of chronic fibrosing infection

Extranodal NK/T-Cell Lymphoma, Nasal Type

- Lymphoid infiltrate with prominent necrosis may resemble lymphomatoid granulomatosis
- EBV positive, but lacks B-cell markers
- Cells express CD3, CD56, and cytotoxic markers

Peripheral T-Cell Lymphoma, NOS

- Atypical mature T-cell infiltrate, either CD4 positive or CD8 positive
- T cells show cytologic atypia
- Clonal T-cell receptor gene rearrangement positive
- EBER-positive cells absent or rare
- Lymph node involvement or other evidence of systemic disease often present

Inflammatory Pseudotumor of the Lung

- Usually a single pulmonary lesion
- Mixed inflammatory infiltrate without atypia
- Polyclonal plasma cells abundant
- Fibrosis common, but necrosis absent

Wegener's Granulomatosis

- Areas of geographic necrosis surrounded by palisading granulomas
- Inflammatory infiltrate contains abundant neutrophils, including neutrophilic microabscesses
- Fibrinoid vascular necrosis is uncommon
- Capillaritis is a helpful diagnostic feature

Allergic Angiitis and Granulomatosis (Churg-Strauss Syndrome)

- Necrotizing vasculitis with eosinophilic pneumonia
- Granulomatous inflammation with giant cells
- Lymphocytes relatively sparse
- Changes of chronic asthma in bronchioles

Interstitial Pneumonia

- Underlying lung architecture intact without nodular lesions
- Interstitial infiltrate of lymphocytes, histiocytes, and fibroblasts; varies according to type of primary pathology

Although HHV-8 continuous presence is required for tumor growth, infection alone is insufficient to induce tumorigenesis and other cofactors are needed. These mostly include iatrogenic immune suppression, coinfections (HIV), and genetic predisposition, which lead to inadequate T-cell surveillance and inflammation. Polymorphisms in specific HLA subtypes or in genes regulating

immune responses might contribute to the susceptibility to develop this disease.[152,153] Therefore, HHV-8 causes a spectrum of lymphoid proliferations only in a small subset of individuals, ranging from reactive lymphoid hyperplasia to overt lymphoma. These include HHV-8-positive germinotropic lymphoproliferative disorder (GLPD), primary effusion/extracavitary lymphoma (PEL/EC-PEL), and HHV-8-positive diffuse large B-cell lymphoma, NOS (HHV-8+DLBCL). Most, except GLPD, occur in severely immunocompromised individuals. HHV-8 can also trigger Kaposi sarcoma inflammatory cytokine syndrome, bone marrow failure, and hepatitis. It has become apparent that the morphologic spectrum of HHV-8-related lymphoid proliferations is broader than previously recognized, and there may be considerable overlap between these entities.[34,57,154,155] For example, it may be difficult to differentiate between EC-PEL and HHV-8-positive DLBCL, NOS. An accurate diagnosis of each HHV-8-related LPD is reached by correlation with clinical and pathologic findings, including virus identification in formalin-fixed paraffin embedded (FFPE) tissue sections using an antibody to LANA.

Multicentric Castleman Disease

Definition of the Disease

HHV-8-associated multicentric Castleman disease (HHV-8-MCD) is a tumor-like lesion with B-cell predominance[57] with similar morphology to idiopathic MCD (discussed in more detail in **Chapter 8**). Likewise, it may manifest inflammatory symptoms caused by hypercytokinemia. A characteristic feature is the presence of HHV-8-infected plasmablasts demonstrated by staining for HHV-8 LANA.

Particularly important are IL-6 produced by the virus (vIL-6), in addition to human interleukin-6 (huIL-6) and IL10.[150,156-158] Viral IL-6 promotes cell proliferation, angiogenesis, and human IL-6 secretion.[154] Linked to elevated HHV-8 viral load and cytokine levels, patients present with recurrent flares of inflammatory symptoms, widespread lymphadenopathy (axillary, abdominal, pelvic, mediastinal, cervical), and splenomegaly. Bone marrow involvement occurs in a significant proportion of cases.[159] Common laboratory abnormalities include cytopenias, hypoalbuminemia, hypergammaglobulinemia, and elevated C-reactive protein.[150,154,158]

Table 28-1

BM, Bone marrow; *CHL,* classic Hodgkin lymphoma; *CNS,* central nervous system; *DLBCL,* diffuse large B-cell lymphoma; *DLBCL-CI,* diffuse large B-cell lymphoma associated with chronic inflammation; *EBV,* Epstein-Barr virus; *EBVMCU,* Epstein-Barr virus–positive mucocutaneous ulcer; *FA-DLBCL,* fibrin-associated diffuse large B-cell lymphoma; *GI,* gastrointestinal; *HIV,* human immunodeficiency virus; *HRS,* Hodgkin and Reed-Stenberg; *LAD,* lymphadenopathy; *LN,* lymph node; *TB,* tuberculosis; *THRBCL,* T-cell/histiocyte–rich B-cell lymphoma.

* Detailed in **Chapter 24**.

HHV-8-positive MCD occurs most commonly (~90%) in HIV-infected males (median age of 42 years), who may also manifest Kaposi sarcoma or non-Hodgkin lymphoma.[155,160-163] Its incidence appears to increase in HIV settings, affecting older individuals more

frequently, with well-preserved immune function, low HIV viral load, and median CD4-positive T-cell count of 150 to 300 cells/mL.[164] Left untreated, the median survival is 2 years, but improved outcomes are seen with newer therapies including rituximab, anti-IL6, and antiretroviral therapy in HIV-positive patients.[163,165] A subset of these individuals will meet the criteria for TAFRO syndrome, characterized by thrombocytopenia, ascites, fever, reticulin fibrosis in bone marrow, organomegaly, and normal amounts of γ-globulin.[166,167]

WHO proposed 5th ed.: KSHV/HHV8-associated multicentric Castleman disease

Pathology

Histology in lymph node and spleen is similar to that seen in idiopathic MCD (see **Chapter 8**), usually with mixed or plasmacytic patterns. The lymph nodes are variably hypertrophic or atrophic and show hyalinized follicles, interfollicular vascular proliferation, and prominent mature plasma cells in the interfollicular zones (**Fig. 28-13A–D**), which may contain cytoplasmic inclusions (Russell bodies) or crystalline forms. Follicles may demonstrate "onion-skinning" of mantle cuffs, and prominent penetrating venules typical of Castleman disease. Characteristic plasmablasts are present either singly, in small clusters, or larger aggregates formerly called "microlymphomas." They are located mostly in or close to the mantle

zones of germinal centers, but may be seen in intrafollicular or perifollicular locations.[168,169] Occasionally, foci of Kaposi sarcoma can be seen in the same lymph node. The malignant cells infected with HHV-8 correspond to IgM-producing B cells without somatic hypermutations. The malignant cells of extracavitary PEL may appear similar in appearance, but in that lymphoma, EBV is usually positive, and the immunoglobulin genes are hypermutated. Bone marrow usually show polytypic plasmacytosis, with a variable number of scattered interstitial HHV-8-positive plasmablasts.[159]

Phenotypically, the plasmablasts are LANA positive and monotypic IgM lambda (**Fig. 28-13E–F**). They usually express CD19, OCT2, CD38, and IRF4/MUM1 and are negative for CD20, PAX5, CD79a, BCL6, CD138, CD30, and EBER. A subset is positive for vIL-6.[170,171] Despite infection of Igκ naïve B cells, HHV-8 induces a BCR revision and phenotypic shift to Igλ expression.[172] The infected cells proliferate and acquire a plasmablastic phenotype mainly in response to IL-6.[169,173] These plasmablasts, although monotypic IgMλ, are polyclonal and do not harbor somatic mutations in the rearranged immunoglobulin genes.[169] Follicles show usually a tight, concentric CD21-positive or CD23-positive follicular dendritic cell meshwork (**Fig. 28-13G**). The interfollicular plasmacytosis is polytypic for immunoglobulin light chains.

With disease progression, the HHV-8-positive plasmablasts may expand to form clusters or aggregates, within or outside the follicles, which are always λ-restricted (**Fig. 28-14**) but polyclonal or oligoclonal by PCR analysis.

HHV-8-Positive Germinotropic Lymphoproliferative Disorder

Definition of the Disease and Clinical Features

HHV-8-positive germinotropic lymphoproliferative disorder (GLPD) is a rare lymphoproliferation characterized by colonization of germinal centers by large atypical lymphoid cells positive for HHV-8, and often coinfected with EBV. It usually presents with slow-growing localized cervical lymphadenopathy in elderly, immunocompetent patients.[162,171,174-178] It may involve multiple sites without bone marrow disease. Rare cases have been reported in association with HIV, usually in younger males.[176] HHV-8-GLPD follows an indolent course with favorable response and stable disease either untreated or subsequent to radiation, rituximab, or chemotherapy.[178] Rare cases have developed HHV-8-positive or EBV-positive DLBCL, NOS.[176,179]

Pathology

Morphologically, the overall lymph node architecture is retained. The germinal centers are variably expanded by large cells with plasmablastic, immunoblastic, or anaplastic features (**Fig. 28-15**), which may extend into mantle zones, interfollicular areas, and sinuses. Marked interfollicular polytypic plasmacytosis and Castleman-like changes may be observed. The atypical cells are negative for CD45, B-cell antigens (CD19, CD20, CD79a, PAX5), germinal-center markers, CD138, and CD30. They are usually positive for IRF4/MUM1 and variably express CD38 and EMA. Aberrant CD3 immunostaining can be seen and PD-L1 expression has been reported.[162,176,180] The large cells are enmeshed in CD21-positive follicular dendritic cell meshworks. They show monotypic light chain in most cases, despite common demonstration of a polyclonal pattern of immunoglobulin gene rearrangement with rare monoclonal cases reported in HIV-positive individuals.[162,174,176,178] The atypical cells are coinfected with both HHV-8 and EBV (latency type I) and have somatic hypermutations indicating germinal-center origin. Their genomic alterations are not currently known given the rarity.

HHV-8-Positive Diffuse Large B-Cell Lymphoma, NOS

Definition of the Disease

HHV-8-positive DLBCL, NOS is a large B-cell lymphoma that is HHV-8 positive and does not fulfill the criteria for a primary effusion lymphoma.

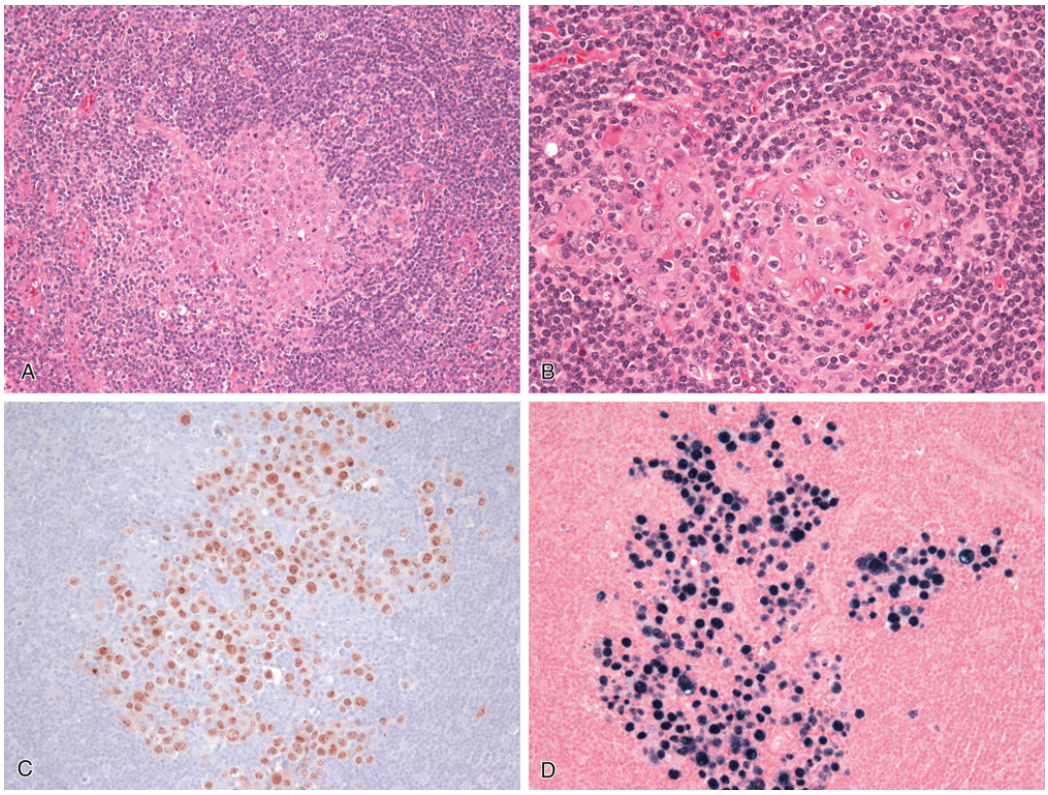

FIGURE 28-15 Human herpesvirus 8–positive germinotropic lymphoproliferative disorder. Germinal centers and mantle cuff contain large blastic cells (**A** and **B**) that are positive for HHV-8 and EBV (**C** and **D**).

Synonyms and Related Terms

WHO revised 4th ed.: HHV8-positive DLBCL, NOS
WHO proposed 5th ed.: KSHV/HHV8-positive DLBCL

Clinical Features and Pathology

This aggressive neoplasm mainly occurs in HIV-positive males aged 30 to 40 years. It is frequently associated with Kaposi sarcoma or

HHV-8-associated MCD. It involves lymph nodes and spleen, and occasionally spreads to extranodal sites including bone marrow and peripheral blood.[160,162,168,171,179] The architecture is effaced by sheets or confluent clusters of plasmablasts or immunoblasts, which are HHV-8-positive (**Fig. 28-16**). EBER is usually negative, but positive cases have been reported.[162,181] The malignant cells resemble immunoblasts or plasmablasts, and have vesicular nuclei, one or more prominent nucleoli, and amphophilic cytoplasm. Rare cases mimic intravascular or Hodgkin lymphoma.[179,182]

The phenotype is similar to the HHV-8 positive plasmablasts in MCD, but they are monoclonal B-cells and express IRF4/MUM1, IgM, and λ light chain. They are variably positive for CD45, B-cell markers (CD20, CD79a), and CD30, and lack PAX5, CD138, and CD38.[162,171,179] Unlike MCD, the plasmablasts demonstrate monoclonal IGH rearrangement, but lack somatic hypermutations. This lymphoma is thought to arise from naïve B cells (IgM positive, CD27 negative, and CD138 negative) with nonmutated Ig variable region genes.[183] It may be challenging to distinguish HHV-8-positive DLBCL from extracavitary PEL. However, the neoplastic cells in PEL are hypermutated, usually EBV positive and CD138 positive, and lack cytoplasmic immunoglobulin expression.

Primary Effusion Lymphoma

Definition of the Disease

Primary effusion lymphoma (PEL) is a B-cell neoplasm characterized by malignant effusions, usually involving pleural, peritoneal, or pericardial cavities, without a detectable tumor mass. In some cases, a mass may be present directly related to the body cavity such as a

pleural-based mass. PEL is always positive for HHV-8, and usually coinfected with EBV. EC-PEL is a related entity presenting with a tumor mass in the absence of effusion. The association between HHV-8 and PEL was first demonstrated by screening a large group of HIV-related lymphomas with molecular techniques.[184] HHV-8 sequences are present in greater copy number compared with Kaposi sarcoma cases. By electron microscopy, viral particles (100- to 115-nm capsids with central cores) can readily be identified within the nucleus and cytoplasm of the neoplastic cells (**Fig. 28-17A**).[185-187] The virus is demonstrated by immunohistochemistry in FFPE tissue sections with an antibody to LANA (**Fig. 28-17B**).

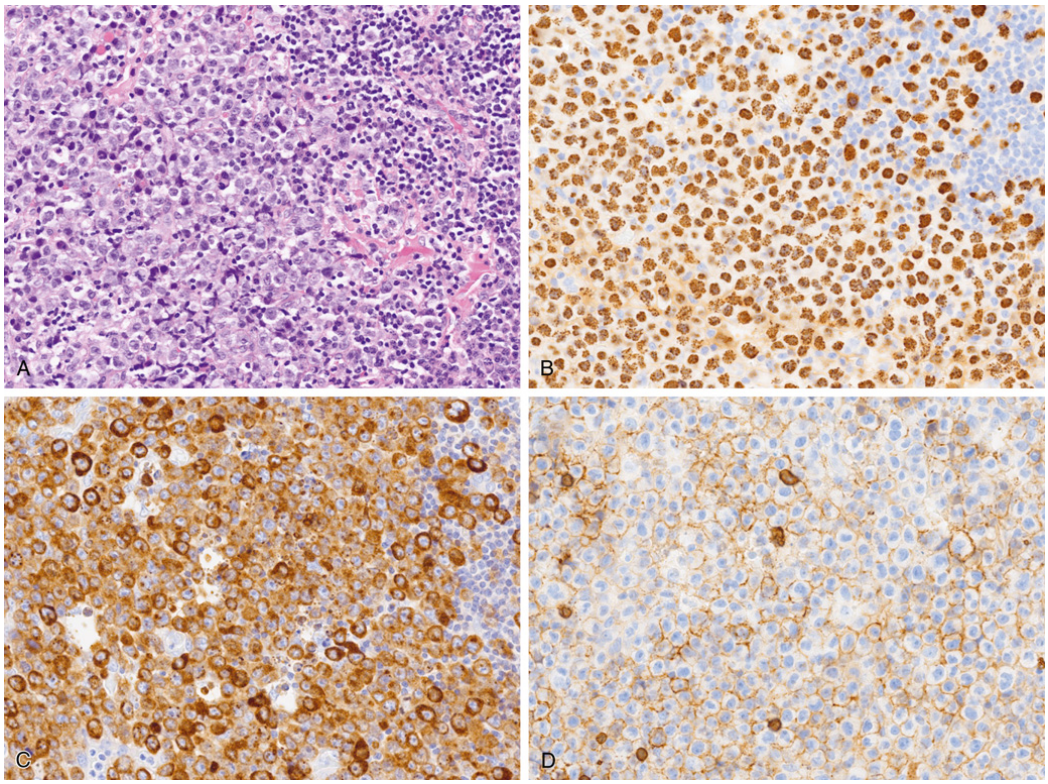

FIGURE 28-16 Human herpesvirus 8–positive diffuse large B-cell lymphoma, not otherwise specified in a patient with multicentric Castleman disease.A, Sheets of large immunoblasts and plasmablasts with amphophilic cytoplasm and frequent mitoses are shown. Residual nonatypical lymphocytes and mature plasma cell expansion are also noted. **B,** Large malignant B cells are uniformly infected with HHV-8 as demonstrated by the latency-associated nuclear antigen (LANA) stain. **C,** Lymphoma cells demonstrate monoclonal cytoplasmic IgM staining. **D,** They show focal and weak expression of CD20.

Synonyms and Related Terms

None.

Epidemiology and Clinical Features

Most cases occur in immunocompromised individuals with HIV infection, and PEL accounts for 1% to 4% of HIV-related lymphomas. Male homosexual contact and IV drug use are among the most common risk factors.[188,189] It has also been documented after bone marrow or solid organ transplantation.[171,190-194] Rare cases occurred in elderly patients (median age 73 years) without a setting of immunosuppression other than age, most often originating from regions endemic for HHV-8, such as the Mediterranean and sub-Saharan Africa.[195-198] It is more prevalent in men (90%), with a median age of 55 years. Patients are usually severely immunosuppressed (CD4-positive T cells ≤200 × 10^6/L) and most have prior AIDS manifestations, including opportunistic infections.[199,200] At presentation, 30% to 50% of patients may have Kaposi sarcoma or MCD.[155,199,201,202]

Neoplastic effusions are usually localized to a single body cavity (pleural, pericardial, or peritoneal), without a contiguous or extracavitary tumor mass.[201,203-205] Symptoms vary from dyspnea and chest pain to heart failure and abdominal distension caused by ascites. Extension to adjacent organs (lung, soft tissues, and regional nodes) or to bone marrow may occur in advanced disease.[206] A subset of patients experiences KSHV inflammatory cytokine syndrome (KICS) with increased KSHV/HHV-8 viral load, IL-6, vIL-6, IL-10, hypoalbuminemia, and thrombocytopenia.[155,207] The prognosis is poor, but chemotherapy and antiretroviral therapy have

resulted in improved outcome.[155,188,199,200,208,209] EBV positivity has been associated with better survival in HIV patients with PEL.[155]

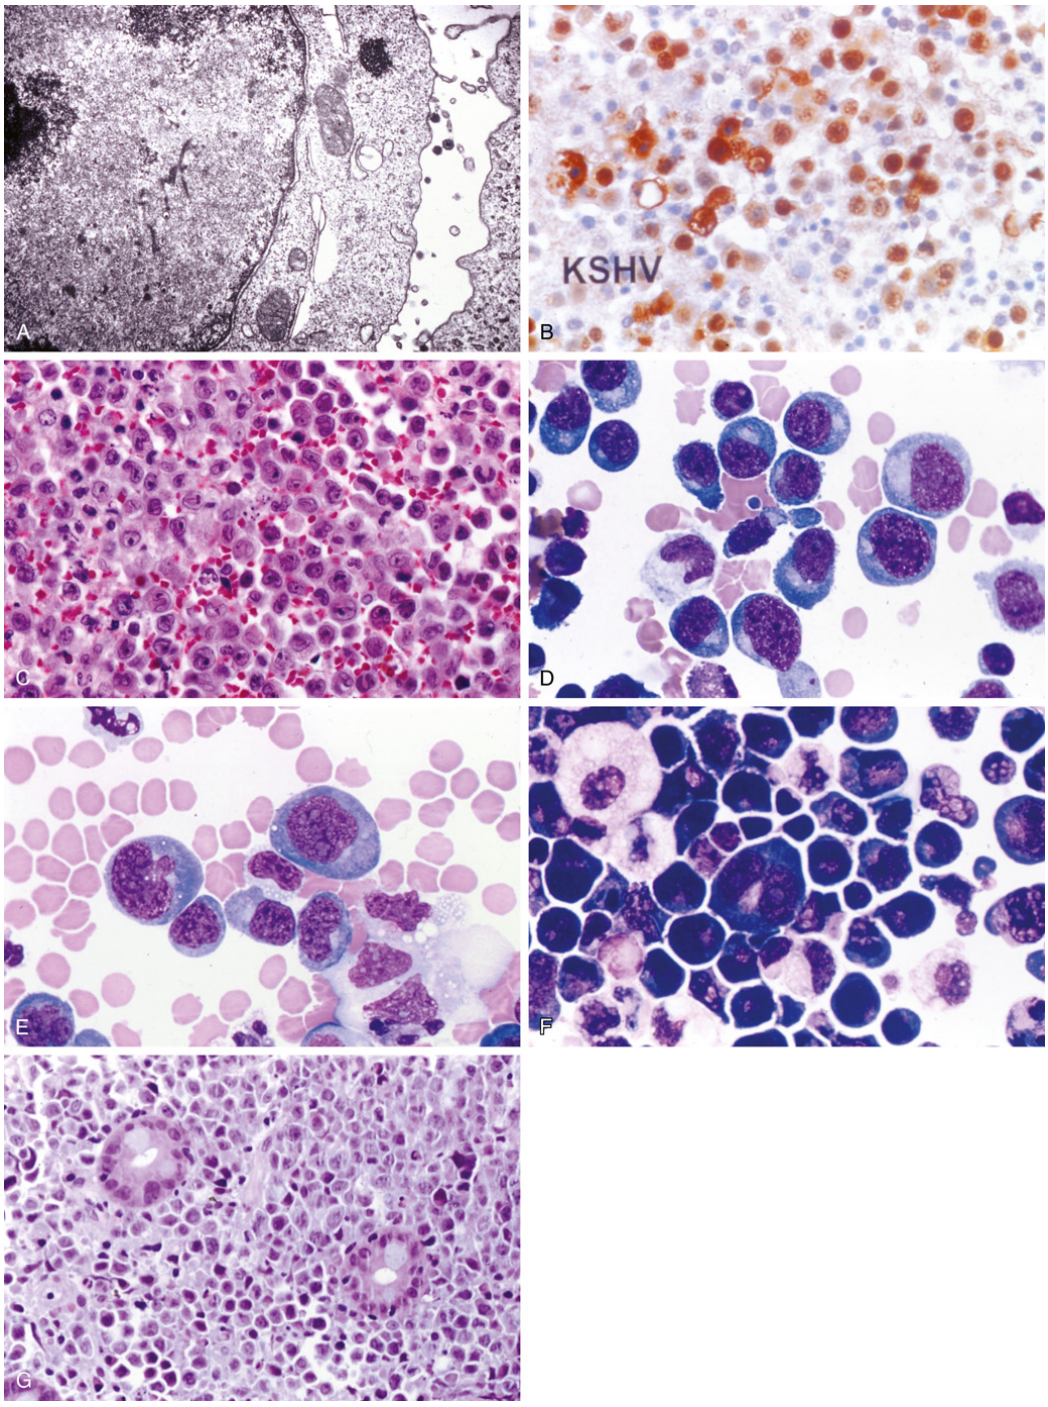

FIGURE 28-17 Primary effusion lymphoma.A, Ultrastructural appearance of primary effusion lymphoma (PEL) cell. There are numerous herpesvirus particles in the nucleus and cytoplasm, with complete virions being shed

from the cell surface (uranyl acetate, lead citrate). **B,** Kaposi sarcoma-associated herpesvirus (KSHV) label on image indicates PEL cells stained for human herpesvirus 8 (HHV-8) latency-associated nuclear antigen (LANA-1/ORF-73) by immunoperoxidase technique in a cell button from pleural fluid (hematoxylin counterstain). **C,** Cell button shows large pleomorphic cells with prominent nucleoli. **D,** Effusion shows plasmacytoid cells with large blastic nuclei (Giemsa stain). **E,** Effusion shows cells with features of plasmacytoid immunoblasts and anaplastic large cell lymphoma. **F,** PEL exhibits anaplastic and Reed-Sternberg–like cells (Giemsa stain). **G,** HHV-8-positive extracavitary primary effusion lymphoma of the bowel is shown.

Pathology

PEL is typically diagnosed by cytologic examination of effusion fluid. Cells are large or display a marked variation in cell size and range from immunoblastic or plasmablastic to more anaplastic morphology. They show polyploid and lobated nuclei, prominent nucleoli, and abundant basophilic cytoplasm, sometimes with paranuclear Golgi hof and vacuoles (**Fig. 28-17C–E**). Occasional multinucleated Reed-Sternberg–like cells may be seen (**Fig. 28-17F**). Phagocytic macrophages and mitotic figures are numerous. Similar morphologic features are observed in the associated solid-

tumor masses, but the marked polymorphism seen in cytology may be less evident in the tissue sections.[210]

Immunophenotypically, the neoplastic cells are usually CD45 positive, but lack surface and cytoplasmic immunoglobulins. CD45-negative cases may be mistaken for carcinoma. As reflection of post–germinal-center B-cell origin and plasmablastic differentiation, PEL cells usually express CD38, CD138, VS38c, IRF4/MUM1, and BLIMP1 and lack pan–B-cell antigens (CD20, CD19, CD79a, OCT2, BOB.1, and PAX5).[162,171,201,210-212] They commonly express activation-associated antigens, such as HLA-DR and CD30 (70%), and variably EMA.[213] Rare cases of PEL may show aberrant expression of T-cell markers or focal positivity for keratins.[187,199,214-216] They are usually BCL6 negative and have a high Ki67 proliferation index. By definition, the neoplastic cells are LANA positive, with a subset of cells labeled by vIL-6. In HIV patients, EBV-infected tumor cells disclose a latency type I pattern ($EBER^{+}EBNA1^{+}LMP1^{-}EBNA2^{-}$). Flow cytometry analysis may suggest PEL diagnosis, but a definitive diagnosis requires demonstration of HHV-8.[217]

Pathogenesis

HHV-8 is the etiologic agent in PEL and most tumor cells express a latent viral pattern, with a subset showing lytic phase genes.[218] The viral latent proteins LANA-1, LANA-2 (vIRF3), vCyclin D1, vFLIP, Kaposin B, and v-IL6 are considered to play important roles in oncogenesis.[154,189,219,220] In addition, the neoplastic cells show strong genetic dependency on cellular *IRF4, MDM2, CCND2, MCL1,* and *CFLAR* (c-FLIP).[221] However, HHV-8 alone is not able to

transform mature B cells in culture and abnormalities of host immunity are critical pathogenetic players.[155,199,222-224] There is evidence that PEL may be poorly controlled in vivo because of inefficient recognition and killing by the T cells.[225] In addition, LANA-2 and PD-L1 expression contribute to neoplastic cells immune evasion.[77,226] Furthermore, proteins specifically involved in the inflammatory/immune response were enriched in the PEL secretome (cell-conditioning media) by proteomic analysis.[227,228] In HIV-positive patients, PEL is almost invariably associated with EBV, but EBV is not required for its pathogenesis.[221,229,230] Interestingly, despite the EBV genetic variability, individual PEL cases harbor a single EBV strain, consistent with monoclonality of infection, and suggesting that EBV infection preceded clonal expansion.[231]

Genetics

Immunoglobulin genes are clonally rearranged in most cases.[187,218] Cytogenetic studies reveal complex chromosomal abnormalities, with recurrent trisomy 7, trisomy 12, and aberrations in the proximal long arm of chromosome 1 (1q), but no *MYC* or *BCL6* gene rearrangements.[199,201,232,233] The gene-expression signature in PEL is closely related to plasmablastic differentiation and shows overexpression of genes involved in inflammation, cell adhesion, or invasion.[234-236] A downregulation of tumor suppressor miRNAs such as miR-155, miR-220/221, or let-7 family has been reported.[237] The mutational signature of PEL cell lines is dominated by the overactivity of the *APOBEC* gene family (APOBEC3B and APOBEC3B3C) engaged in innate immune defense against viruses.[238] In addition, PEL tumor cells show recurrent interleukin 1

receptor-associated kinase 1 (IRAK1) Phe196Ser mutation, which is essential for PEL survival in vitro and provides reasoning for therapeutic use of IRAK1/4 inhibitors.[239,240] Furthermore, strong dependency on cyclin D2 and MCL1 render PEL cell lines sensitive to specific inhibitors.[221]

Differential Diagnosis

Lymphomas presenting as effusions in the absence of a tumor mass are unusual, and only PEL is associated with HHV-8. PALs typically present as a pleural-based mass in elderly males who are HIV negative. Despite the plasmacytoid differentiation, PAL cells express B-markers; most are EBV positive but HHV-8 negative. HHV-8-negative and EBV-negative primary effusion-based lymphoma (WHO proposed 5th ed. *fluid overload-associated large B-cell lymphoma*) is not associated with HHV-8 and occurs in HIV-negative elderly patients (median age 70 years) with fluid overload states such as cirrhosis secondary to hepatitis C infection or cardiac disease.[241-243] It has a better prognosis than PEL. This neoplasm expresses B-cell–associated antigens and, using more loosely defined criteria, a subset of cases have been reported to be EBV positive or demonstrate *MYC* abnormalities.[242,244] Occasionally, plasmablastic lymphoma and Burkitt lymphoma in HIV patients may involve body cavities. PBL may be indistinguishable morphologically and immunophenotypically from PEL, but usually has cytoplasmic immunoglobulin expression and lacks HHV-8. Burkitt lymphoma show a characteristic phenotype, *MYC* gene rearrangement, and is not associated with HHV-8. Distinction of PEL from other cytologic mimickers such as undifferentiated carcinoma, anaplastic large cell

lymphoma, plasmablastic myeloma, or ALK-positive large B-cell lymphoma is facilitated by the clinical presentation and immunophenotype. To accurately diagnose PEL, a combination of clinical, morphologic, and phenotypic studies is required, together with confirmation of HHV-8 either by polymerase chain reaction (PCR) or with LANA antibody.

Extracavitary Primary Effusion Lymphoma

EC-PEL manifests as a tumor mass without an effusion. It most often involves lymph nodes, gastrointestinal tract (**Fig. 28-17G**), skin, and lung, with rare cases described in the CNS and bone marrow.[162,171,183,199,214,242,245-249] It may also localize in intravascular spaces, mimicking a metastatic carcinoma, anaplastic large-cell lymphoma, or intravascular large B-cell lymphoma.[171,179,183,250,251] The demographic and epidemiologic features of extracavitary lesions closely resemble those of PEL, but they appear to affect less-immunosuppressed HIV-infected patients and have a higher disease-free survival.[199,212] Cells of EC-PEL are similar to PEL but occur in sheets. Lymph node architecture is usually effaced, but involvement may be partial or sinusoidal. The neoplastic cells may lack CD45 and express B-cell antigens (CD20, CD79a) and immunoglobulin more often than the typical PEL.[212,214,249] Similarly, it may show an aberrant expression of T-cell markers, which can lead to misdiagnosis.[199] Overlap may occur between EC-PEL and HHV-8-positive DLBCL, NOS. Unlike other plasmablastic-appearing lymphomas, it contains both EBV and HHV-8.

Table 28-2 contrasts the key features of HHV-8-related lymphoid proliferations including MCD, HHV-8-positive GLPD, HHV-8-positive DLBCL, NOS, PEL, and EC-PEL.

Kaposi Sarcoma Involving Lymph Nodes

Kaposi sarcoma may involve the lymph nodes, even in the absence of skin lesions. This is discussed further in **Chapter 57**.

Pearls and Pitfalls

- When diagnosing an Epstein-Barr virus (EBV)–related lymphoproliferative disorder, EBV should be expressed by a majority of the atypical cells and not by the background infiltrate.
- Hodgkin/Reed-Sternberg–like cells are commonly present in EBV-related lymphoproliferative disorders, and the differential diagnosis from classic Hodgkin lymphoma may be challenging.

- Chronic active EBV disease is restricted to the T/natural killer (NK)-cell–derived cases.
- EBV-positive diffuse large B-cell lymphoma, not otherwise specified (DLBCL, NOS) can occur at any age, including young patients, without apparent features of immunodeficiency.
- EBV-positive mucocutaneous ulcer should be considered in the differential diagnosis of any solitary EBV-positive lymphoproliferative disorder involving cutaneous or mucosal sites.
- Lymphomatoid granulomatosis requires lung involvement.
- EBV-positive lymphoproliferative disorders may have an aberrant phenotype with expression of T-cell antigens or CD15.
- EBV-positive polymorphic B-cell lymphoproliferative disorder, NOS can be used for EBV related B-cell proliferations that do not fulfill the criteria of a well-defined lymphoma. It should not be used for cases of EBV reactivation or typical cases of infectious mononucleosis. It can be used in cases with insufficient or low-quality material that prevent a more definitive diagnosis.
- HHV-8-positive lymphoproliferative disorders include a spectrum of disorders which may show overlapping features and their differential diagnosis may be difficult.
- Plasmablasts in HHV-8-associated MCD are light-chain restricted and express IgM lambda in all cases, but they are polyclonal.

- Staining for HHV-8 latency-associated nuclear antigen (LANA) is essential to identify primary effusion lymphoma (PEL) and extracavitary PEL cases given that similar morphology may be encountered in other lymphomas, including some that may also present with effusions.
- HHV-8-positive germinotropic lymphoproliferative disorder shares some features with extracavitary PEL, but lacks immunoglobulin gene rearrangements.

INTRODUCTION

Epstein-Barr virus (EBV) is a ubiquitous herpesvirus with tropism for B cells. More than 90% of humans are infected with EBV, and the infection persists for life. Usually primary infection is asymptomatic and occurs early in life, and when symptomatic is usually a self-limited disease occurring in adolescents or young adults manifested as acute infectious mononucleosis (AIM). AIM is characterized by a polyclonal expansion of infected B cells and a cytotoxic T-cell response composed of a transient, antigen-driven oligoclonal expansion of CD8-positive T cells. Both the quantity and quality of the CD8-positive T-cell response to EBV are critical to control the infection. In vivo EBV is capable of infecting, in addition to B cells, T cells and natural killer (NK) cells, as well as epithelial and mesenchymal cells. The infection of T cells and NK cells may lead to several EBV-related lymphoproliferative diseases, with disease manifestations generally depending on the type of EBV-infected cells and the state of host immunity.

EBV-positive T-cell and NK-cell lymphoproliferative disorders encompass disease entities with a broad clinicopathologic spectrum. The term *T/NK-cell chronic active EBV infection* has been used in the literature to encompass a broad spectrum of diseases comprising a systemic polyclonal or monoclonal form (T cells; αβ or γδ cells, and NK-cells) and a cutaneous form, including hydroa vacciniforme–like lymphoproliferative disorder (usually of T-cell origin) and severe mosquito bite allergy (usually of NK-cell origin).[1-3] The systemic form was termed *chronic active EBV infection* in the early literature and in the 4th and the revised 4th editions of the *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues* (WHO 4th ed., revised WHO 4th ed.)[4,5] and renamed as *chronic active EBV*

disease (CAEBVD) in the *International Consensus Classification* (ICC)[6] and the 5th edition of the *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues* (WHO 5th ed.)[7]; because around 95% of the world population are chronically, latently infected, but only few acquire the disease, the term *CAEBVD* is preferred.[6]

Hydroa vacciniform lymphoproliferative disease (HVLPD) replaced the term *hydroa vacciniforme-like LPD* of the revised WHO 4th ed.[5] New studies have shown that "classic" HV in Western countries is also associated with EBV, and therefore, all HV cases belong within the spectrum of the same disease.[8-10] In the ICC and WHO 5th ed., HVLPD is divided into a classic and a systemic form based on the presence or absence of severe systemic symptoms.[6,7] Systemic HVLPD eventually might require similar treatment as CAEBVD.

Systemic EBV-positive T-cell lymphoma represents the fulminant form of a clonal EBV-infected T-cell proliferative disease occurring after primary EBV infection or, less often, after CAEBVD. The WHO 4th ed. recognized systemic T-cell lymphoproliferative disorder of childhood as a neoplasm; to clarify the aggressive nature of this disease, the term was changed to *systemic EBV-positive T-cell lymphoma* in the revised WHO 4th ed.[5]

Systemic EBV-positive T-cell lymphoma shares clinical and pathologic features with aggressive NK-cell leukemia, but they differ in the lineage; the former is of T-cell origin, whereas the latter is of NK-cell origin. A rather difficult differential diagnosis and often overlapping disease is EBV-associated hemophagocytic lymphohistiocytosis (HLH) in childhood, which is a

hyperinflammatory syndrome induced by dysregulated immune reaction secondary to EBV infection. Although clonal EBV-infected T cells have been demonstrated in some cases, patients usually respond to treatment, which can be limited in some cases, and recover completely after the acute disease.

Aggressive NK-cell leukemia and extranodal NK/T-cell lymphoma, nasal type (ENKTL-NT) are recognized as the prototypes of EBV-positive T-cell or NK-cell lymphoma/leukemia in the WHO 4th ed.[11] ENKTL-NT primarily involves extranodal sites, mainly the upper aerodigestive tract. Primary nodal EBV-positive T/NK-cell lymphoma is an EBV-positive cytotoxic T-cell or NK-cell lymphoma primarily involving the lymph nodes. It is an uncommon disease, now introduced as a provisional entity in the ICC, and as a definitive entity in the WHO 5th ed.[6,7] This chapter details the clinicopathologic features of all these disease entities (**Box 29-1**).

Box 29-1 Classification of EBV-Associated T-Cell and NK-Cell Lymphoproliferative Disorders

Epstein-Barr Virus–Associated Hemophagocytic Lymphohistiocytosis

Definition

HLH is a clinicopathologic syndrome encompassing a markedly dysregulated immune response and hypercytokinemia. HLH is characterized clinically by fever, splenomegaly, and cytopenias, and is accompanied by histologic evidence of hemophagocytosis, which causes extremely high serum levels of ferritin, lactate dehydrogenase, and soluble CD25.[12,13] (Capsule summary in **Box 29-2**.) The disease is classified into a primary (genetic) form and a secondary (acquired) form. Secondary HLH occurs in the setting of infection or underlying autoimmune disorders or malignancy. EBV-associated HLH (EBV-HLH) accounts for 36% to 44% of all HLHs and the most common infection-associated HLH.[14-16] The diagnosis is established when EBV is documented in the blood or tissue in addition to fulfilling the criteria in the HLH-2004 guidelines.[12] EBV infection can be associated with primary HLH, CAEBVD, T/NK-cell lymphoma/leukemia, or B-cell lymphoma, which should be excluded by genetic test and pathologic examination (**Box 29-2**).

Epidemiology

EBV-HLH is a rare disease. In an observational study in Japan, where HLH is common, annual incidence of HLH is 1 in 800,000 and EBV-HLH accounts for 35% of cases of all HLH.[14] EBV is the most common triggering factor for HLH in children.[16] The median age of children with EBV-HLH is 2.6 years and the male-to-female ratio is equal.[17] In adults, EBV accounts for 15.7% to 40% of the

triggering factor in HLH.[18,19] Median age of patients is 49 years with male predominance.[19,20]

Most reports of EBV-HLH in children are from East Asian countries[14-16] and in indigenous populations of Mexico and South America.[21-23] It has also been reported in Western countries, but at a much lower frequency.[24,25]

Specific geographic distribution of adult EBV-HLH is similar to that of childhood EBV-HLH. This ethnic and geographic distribution indicates that similar genetic factors are involved in the development of secondary EBV-HLH as in other EBV-positive T/NK-cell LPDs.

Box 29-2 Major Diagnostic Features of EBV-Associated Hemophagocytic Lymphohistiocytosis

EBER, EBV-encoded RNA; *EBV,* Epstein-Barr virus; *HLH,* hemophagocytic lymphohistiocytosis; *NK,* natural killer.

Definition

- A hyperinflammatory syndrome induced by dysregulated immune reaction secondary to EBV infection

Diagnostic Criteria

- Demonstration of high EBV load in the blood or tissue
- Fulfilment of HLH 2004 guideline: fever; splenomegaly; cytopenias affecting at least two of three lineages in the peripheral blood; hyperferritinemia; hyperglyceridemia or hypofibrinogenemia; hemophagocytosis in bone marrow,

spleen, or lymph node; low or absent NK-cell activity; high level of CD25. Five of these eight criteria are required for diagnosis.

Clinical Features and Behavior

- Prevalent in Asia
- Usually encountered in the context of primary EBV infection in children (median age, 3.9 years) without underlying disease while adult patients have viral antibodies indicative of past infection or reactivation
- Often fatal but can be effectively controlled in 90% of children by HLH 2004 protocol
- Poor prognostic factor includes hyperbilirubinemia, hyperferritinemia, or cytogenetic abnormality

Morphology

- Hemophagocytic histiocytosis in bone marrow, liver, and spleen
- Infiltration of EBER-positive T cells without atypia in the bone marrow and hepatic sinusoids

Immunophenotype and Genotype

- EBV found mainly in T cells
- Infiltrating T cells express CD8 and granzyme B
- The clonality of EBV-infected T cells is often observed

Pathophysiology

EBV-HLH is primarily a CD8-positive T-cell/macrophage-mediated hyperinflammatory immune reaction driven by EBV infection in the absence of appropriate cytotoxic activity.[26] Primary EBV infection is mostly asymptomatic except for AIM, in which EBV infection in B cells leads to polyclonal B-cell expansion accompanied by antigen-driven proliferation of CD8-positive cytotoxic T cells. In EBV-HLH, EBV ectopically infects CD8-positive T cells[27-29] through the CD21 receptor that can be expressed in mature T cells.[30] In normal individuals with EBV-protective immunity, an expanded EBV-specific CD8-positive T-cell pool is contracted concomitant with the fall in circulating virus loads and back to its normal size.[31,32] In patients with EBV-HLH, deficiencies with impaired T-cell cytotoxicity activity/killing of EBV-infected target cells lead to uncontrolled activation and proliferation of antigen-driven CD8-positive T cells.[33] These activated T cells release excessive IFN-gamma, which leads to continual expansion of CD8-positive T cells, histiocytes, and macrophages.[34] Activated T cells and macrophages infiltrate multiple organs and secrete high levels of inflammatory cytokines, including IL1, IL6, tumor necrosis factor (TNF)-α, and IFN-γ, leading to secondary activation of histiocytes and macrophages.[35,36] This cytokine storm leads to cardinal clinical and laboratory features of HLH. The mechanism leading to impaired protective immunity of EBV and uncontrolled proliferation of T cells in secondary HLH is not well understood. The particular prevalence of EBV-HLH in Asian children suggests that underlying genetic factors contribute to the EBV-related dysregulated immune responses. Studies for primary immunodeficiency-mediated EBV-

HLH disclose mutations involving T-cell activation or the costimulatory pathway, as well as genetic defects in the component of the lytic granule exocytosis pathway, which leads to impaired elimination of EBV-infected target cells and protracted T-cell expansion and activation.[26,33] Monoallelic or missense mutation of genes involved in lymphocyte cytotoxicity has been observed in 60% of nonimmunosuppressed EBV-HLH in the Chinese population.[37] Cytokine gene polymorphisms involving TGF-beta1, IL2RA, and IL10 are highly associated with susceptibility to EBV-HLH.[38,39]

Clinical Features

EBV-HLH is a systemic illness that is usually first detected as a persistent fever that is unresponsive to antibiotics. Patients with EBV-HLH exhibit cytopenias, liver dysfunction, hepatosplenomegaly, and hemophagocytosis in the bone marrow, lymph node, liver, or spleen. Coagulopathy, pleural effusions/ascites, and central nervous system (CNS) disease can also occur. Elevated triglyceride or ferritin levels, low fibrinogen level, low or absent NK-cell cytotoxicity, and elevated soluble CD25 are sometimes seen. EBV viral load in peripheral blood is high and correlates well with disease activity. Serologic study shows that young children with EBV-HLH have elevated VCA-IgM, indicating primary EBV infection,[12-14,35] while adult patients have viral antibodies indicative of past infection or reactivation.[20,40]

Morphology

In patients with EBV-HLH, the bone marrow shows hemophagocytic histiocytes and a variable number of EBV-positive T cells in addition

to myeloid and erythroid cells (**Fig. 29-1**). The liver biopsy shows Kupffer cell hyperplasia, mild infiltration of small T cells in the portal tract and sinusoids, and intrasinusoidal infiltration of hemophagocytic histiocytes. Because of minimal histologic changes in the early stage, diagnostic abnormalities may not be detected with hematoxylin and eosin (H&E) stains. EBV-encoded RNA (EBER) in situ hybridization highlights EBER-positive cells in the bone marrow and hepatic sinusoids.

Immunophenotype and Genetics

Cells infiltrating the bone marrow and liver are cytotoxic T cells that express CD8 and granzyme B or, uncommonly, NK cells.[41,42] In peripheral blood, flow-cytometric analysis may show a significant increase in a subpopulation of CD8-positive T cells that exhibit downregulation of CD5.[29] EBV is best determined by molecular methods that can detect the presence of EBV genomic DNA or EBER in biological specimens such as serum, bone marrow, or lymph nodes. Antigen-driven CD8-positive T cells in EBV-HLH are commonly monoclonal and can regress with immunoregulatory therapy.[29,43,44]

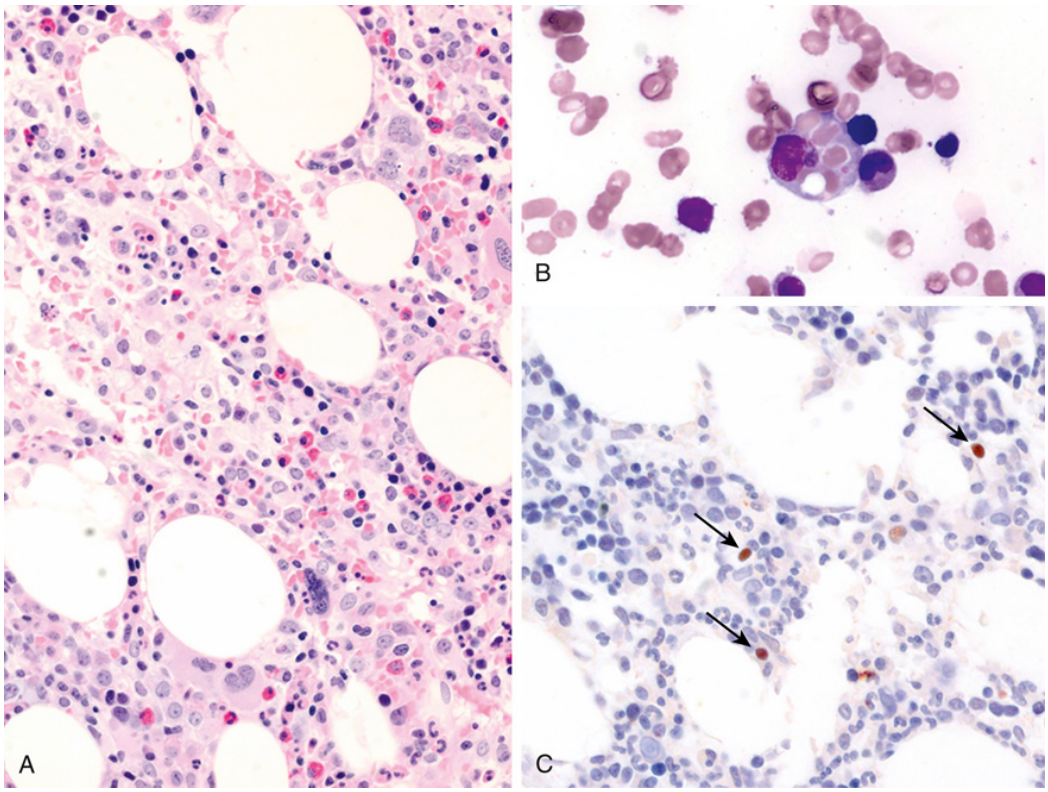

FIGURE 29-1 Epstein-Barr virus–associated hemophagocytic lymphohistiocytosis.A, Bone marrow shows increased cellularity with normal hematopoietic cells and many histiocytes. **B,** Aspiration smear shows erythrophagocytosis. **C,** Epstein-Barr virus (EBV)–encoded RNA in situ hybridization reveals a few EBV-positive small lymphocytes without atypia.

Postulated Cell of Origin

The postulated cells of origin are EBV-infected CD8-positive cytotoxic T cells and, rarely, NK cells.

Clinical Course and Prognostic Factors

EBV-HLH is a heterogeneous disorder with various symptoms that can range from mild to severe. In the past, a significant proportion of patients died because of cytokine storm or disease progression to CAEBVD or EBV-positive systemic T-cell lymphoma of childhood.[15,45] With the HLH-94/2004 combination treatment including etoposide, dexamethasone, and cyclosporine A, EBV-HLH in children without underlying disease can be effectively controlled in more than 90% of patients. However, the other 10% often die of fulminant disease.[42] Patients with hyperbilirubinemia, hyperferritinemia, renal failure, or CNS hemorrhage at diagnosis, or cytogenetic abnormality, have significantly poorer outcomes. The presence of clonality at the time of diagnosis is not associated with a poor outcome, but a change in clonality may be a good marker of disease activity in childhood EBV-HLH.[42,46] Despite appropriate patient management, the outcome of the adult patients is significantly poorer than the pediatric disease and 46% of patients respond to the HLH-94/2004 regimen.[19,47]

Differential Diagnosis

T/NK-cell leukemia/lymphomas can be complicated with EBV-HLH, but show obvious atypia of infiltrating EBV-positive cells. CAEBVD can present with EBV-HLH. A long clinical history compatible with CAEBVD is helpful in the differential diagnosis. EBV-HLH and systemic EBV-positive T-cell lymphoma of childhood share a significant overlap in clinical presentation and pathologic changes.[48] Because EBV-HLH is frequently associated with clonal T-cell populations, the distinction between these two diseases is

challenging. Cytogenetic abnormality may be the only useful marker for distinction.[48,49] Primary HLH that is associated with EBV infection can be excluded by genetic testing and family history.

Chronic Active Epstein-Barr Virus Disease

Synonyms and Related Terms

WHO revised 4th edition: Chronic active EBV infection of T- and NK-cell type, systemic form

WHO proposed 5th edition: Systemic chronic active EBV disease

Definition

Chronic active EBV disease (CAEBVD) is a systemic EBV-positive polyclonal or monoclonal T-cell or NK-cell lymphoproliferative disorder with a wide range of clinical severity and characterized by intermittent or chronic infectious mononucleosis-like symptoms lasting more than 3 months in patients with no known immunodeficiency.[5] (Capsule summary in **Box 29-3**.)

CAEBVD was initially proposed by Straus[50] as a severe illness of greater than 6 months duration that (1) begins as a primary EBV infection or is associated with markedly abnormal EBV antibody titers (e.g., anti-EBV viral capsid antigen [VCA] immunoglobulin [Ig]G ≥5120, anti-EBV early antigen IgG ≥640, or anti–Epstein-Barr nuclear antigen [EBNA] <2); (2) shows histologic evidence of major organ involvement, such as interstitial pneumonia, hypoplasia of the bone marrow, uveitis, lymphadenitis, persistent hepatitis, or

splenomegaly; and (3) exhibits increased EBV RNA or proteins in affected tissues. Later, Kimura and colleagues proposed modified diagnostic criteria for CAEBVD stipulating that patients should have an EBV-related illness or symptoms lasting more than 3 months' duration and increased EBV DNA ($>10^{2.5}$ copies/μg EBV DNA) in peripheral blood mononuclear cells or RNA in the tissue, or grossly abnormal levels of EBV antibodies.[51] In the initial description, it was always thought that CAEBV was a disorder of B cells, but since then, the cases reported in Japan and East Asia have almost always been associated with a proliferation of EBV-infected T cells or NK cells.[52,53] CAEBVD-B lineage has been reported mainly in Western countries[54] and usually a manifestation of underlying primary immunodeficiency[55]; therefore, CAEBVD in the WHO and ICC excludes B-cell lineage and only includes T- or NK-cell disease.[5,6]

Box 29-3 Major Diagnostic Features of Chronic Active Epstein-Barr Virus Disease

CAEBVD, Chronic active EBV disease; *EBV,* Epstein-Barr virus; *Ig,* immunoglobulin; *LPD,* lymphoproliferative disorder; *NK,* natural killer; *VCA,* viral capsid antigen.

Definition

- CAEBVD is a systemic EBV-positive polyclonal or monoclonal T-cell or NK-cell lymphoproliferative disorder

Diagnostic Criteria

- High viral load in peripheral blood or tissues

- Intermittent or persistent infectious mononucleosis–like symptoms such as fever, lymphadenopathy, and hepatosplenomegaly for at least 3 months
- No known immunodeficiency

Clinical Features and Behavior

- Prevalent in Asia and Latin America
- Most patients are children or young adults (median age, 11.3 years; range, 9 months–53 years); adult patients are not uncommon
- Often accompanied by hydroa vacciniforme LPD or severe mosquito bite allergy
- High antibody titers against EBV VCA and early antigen
- Poor prognostic factors: late onset of disease (older than 8 years), thrombocytopenia, EBV infection in T cells
- Cause of death: hemophagocytic syndrome, multiple organ failure, T-cell or NK-cell malignancy

Morphology

- Polymorphic infiltrates of inflammatory cells with or without granuloma and focal necrosis
- No significant atypia in infiltrating lymphocytes
- Sinusoidal infiltration by small lymphocytes without atypia in liver

Immunophenotype and Genotype

- EBV found mainly in T cells and NK cells
- EBV terminal repeat: polyclonal, oligoclonal, or monoclonal
- TR gene rearrangement: polyclonal, oligoclonal, or often monoclonal

Epidemiology

As with other EBV-associated T/NK-cell diseases, CAEBVD has a strong racial predisposition, with most cases reported from East Asia, including Japan, Korea, and China, and Latin America. It occurs uncommonly in Whites and Blacks.[54,56,57]

Pathophysiology

In the primary infection, EBV infects B cells via the cell surface receptor CD21 and EBV-infected B-cell proliferation is normally controlled by an EBV-specific cytotoxic T-lymphocyte (CTL) response. In CAEBVD, T cells or NK cells are the main targets of EBV. T cells and NK cells usually lack the EBV receptor CD21, but normal peripheral T cells express CD21 at low levels,[58] and NK cells can acquire CD21 by synaptic transfer from B cells,[59] allowing EBV to bind to T cell or NK cells during the primary infection. On the other hand, a study showed that EBV can infect human NK cells by direct transfer of viral episome independent of EBV-positive B cells.[60] Unlike classic infectious mononucleosis, EBV-infected T/NK cells are not removed but proliferate to involve multiple organ systems because of defective cellular immunity. Although most patients with CAEBVD have no consistent immunologic abnormality and the diagnostic criteria include the absence of known immunodeficiency, patients with CAEBVD show minor defects in

cellular immunity against EBV. Reduced NK-cell cytotoxicity and impaired EBV-specific CTL activity have been reported in some patients with CAEBVD. This defective T-cell function is not limited to EBV, but low numbers of cytomegalovirus-specific CTLs, and an overall T-cell dysfunction, have also been observed.

In addition, EBV-infected T cells and NK cells evade the immune system through decreased antigen presentation and possibly other immunomodulatory factors. EBV-infected T cells or NK cells in CAEBVD express a limited number of EBV-related antigens, including EBNA1, latent membrane protein-1 (LMP1), and LMP2, but not EBNA2, 3A, 3B, or LP. EBNA1 and LMP1 are less antigenic than other EBNA proteins.

EBV-infected T/NK cells in CAEBVD show constitutive activation of NF-κB and STAT3, which contribute to prolonged cell survival of EBV-positive T/NK cells.[61] EBV genome in CAEBVD patients harbored frequent intragenic deletions that were also common in various EBV-associated neoplastic disorders. The deletion of one of the essential genes, BALF5, resulted in upregulation of the lytic cycle and the promotion of lymphomagenesis in a xenograft model. Mutations of *DDX3X* and other driver genes contribute to clonal evolution of EBV-positive T/NK cells and transformation to lymphoma/leukemia.[62]

Clinical Features

CAEBVD was initially recognized as a disease of children, but according to the recent Japanese nationwide CAEBVD survey, more than half of patients were adults. The median age of disease onset is 21 years, with a range of 1 to 73 years, and the male-to-female ratio is

1.1:1.[63] The symptoms generally consist of prolonged or intermittent fever (93% of patients), hepatomegaly (79%), splenomegaly (73%), thrombocytopenia (45%), anemia (44%), and lymphadenopathy (40%). Cutaneous manifestations are common and include severe mosquito bite allergy (33%), rash (26%), and HV (10%).[51,64,65] Some patients in South America present with periorbital and facial edema, high levels of EBV DNA, and systemic symptoms. The ICC decided to classify these cases as CAEBVD because of its aggressive clinical course and lack of typical HV lesions.[6,66] Life-threatening complications include hemophagocytic syndrome, interstitial pneumonia, malignant lymphoma, coronary aneurysm, CNS involvement, and bowel perforation.[51,64] Most patients have high antibody titers of EBV VCA IgG and early antigen IgG, and they often have IgA antibodies against VCA and early antigen.[52] All patients have elevated levels of EBV DNA in their blood, which is well correlated with clinical severity.[64]

Morphology

In general, patients with CAEBVD do not exhibit changes suggestive of a neoplastic lymphoproliferative process in affected tissues (**Fig. 29-2**). The lymph nodes show variable histologic changes with paracortical hyperplasia, a polymorphic and polyclonal lymphoid proliferation, large numbers of EBER-positive cells, and infiltration with many other inflammatory cells, including plasma cells and histiocytes. Granulomas associated with necrosis may be present. The liver shows portal or sinusoidal infiltration by small lymphocytes without atypia.[52] In cases complicated by hemophagocytic syndrome, histiocytic hyperplasia with erythrophagocytosis can be

seen in the bone marrow, liver, and skin. In cases with monoclonal CAEBVD, the infiltrating cells tend to have slight cytologic atypia and include a higher proportion of EBV-positive cells.

Immunophenotype

The immunophenotype of the EBV-positive cells infiltrating the tissue and circulating in the peripheral blood varies from case to case and includes αβT cells, γδT cells, CD4-positive T cells, CD8-positive T cells, NK cells, or mixtures of these cells (**Fig. 29-2**). Many cells express cytotoxic molecules such as perforin, TIA-1, and granzyme B. Rarely, EBV-infected B cells are also present.

Genetics

EBV is polyclonal, oligoclonal, or monoclonal, as confirmed by terminal repeat analysis. T-cell receptor gene rearrangement is also polyclonal, oligoclonal, or monoclonal. Clonality confirmed by the presence of somatic mutations can be detected in about 30% of CAEBVD cases at diagnosis.[62] CAEBVD is largely accompanied by *DDX3X* mutations, and recurrent mutations also involved other genes, including *KMT2D, BCOR, BCORL1, TET2,* and *KDM6A,* which recapitulate the mutation pattern reported in extranodal NK/T-cell lymphoma. Identical driver mutations are shared by different cell lineages, including T, B, and NK cells.[62] No specific chromosomal abnormality has consistently been shown in CAEBVD to date, but cases with progression to monoclonal T- or NK-cell lymphoproliferative disorders show complex chromosomal aberrations.[64]

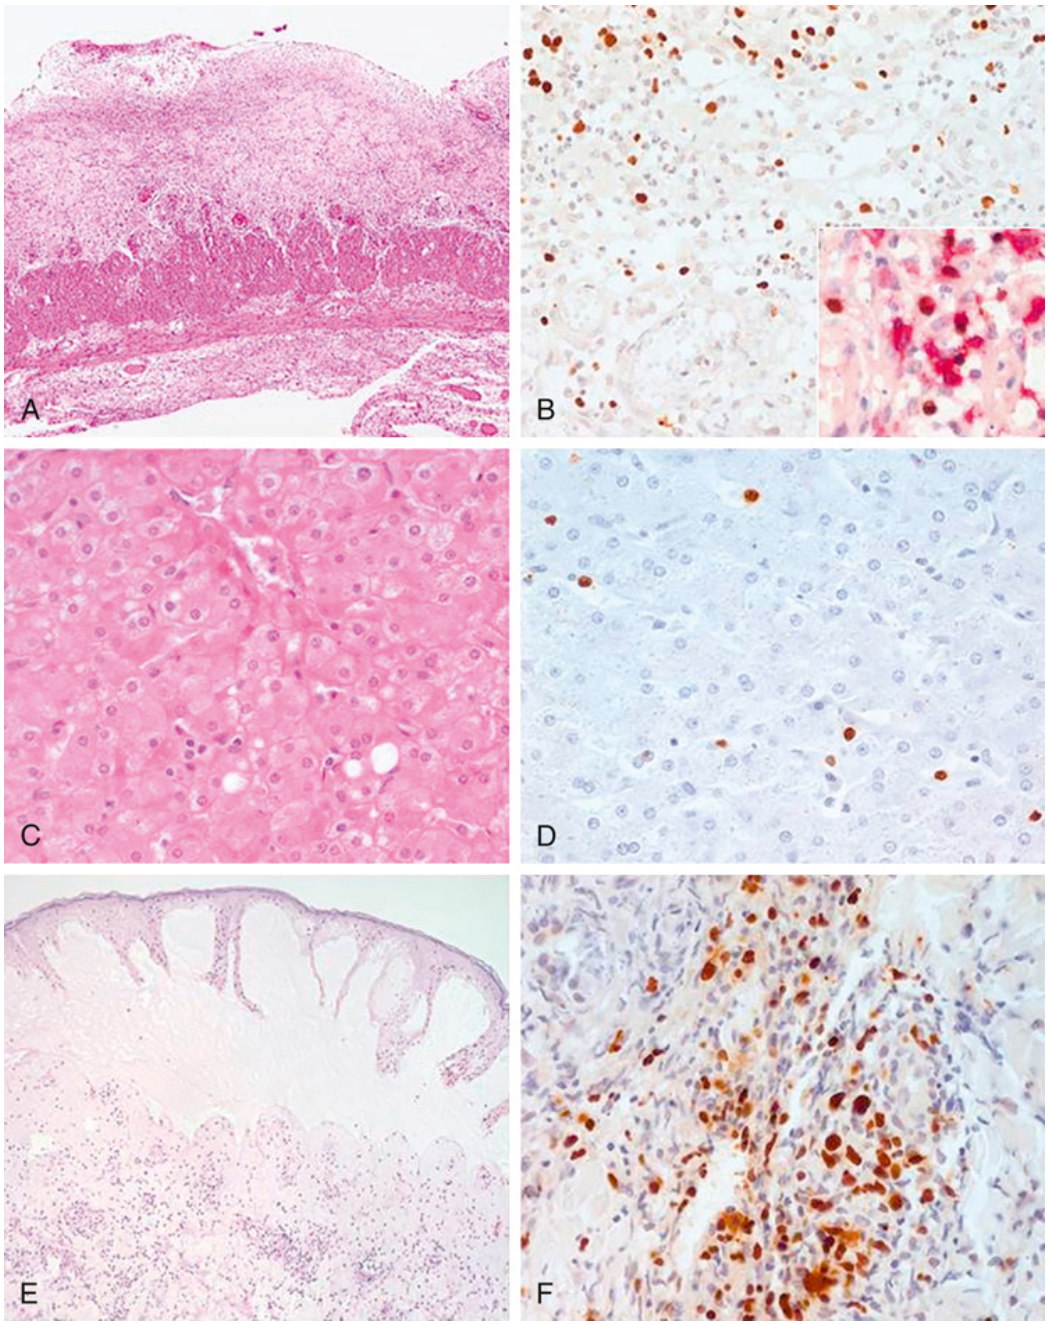

FIGURE 29-2 Chronic active Epstein-Barr virus disease.A, This 5-year-old boy was admitted because of fever, recurrent bowel perforation, abnormal liver function, skin rashes of the face and neck, and natural killer (NK) lymphocytosis for 2 years. Resected bowel shows

granulation tissue infiltrated by small lymphocytes and neutrophils. **B,** Epstein-Barr virus (EBV)–encoded RNA (EBER) in situ hybridization highlights EBV-positive lymphocytes, which are also positive for CD3 *(inset)*. **C,** Liver biopsy of the patient shows minimal histologic change. **D,** EBER in situ hybridization highlights EBV-positive small lymphocytes in hepatic sinusoids. **E,** Skin biopsy reveals suprabasal bulla and perivascular inflammatory infiltration. **F,** EBER is positive in many perivascular lymphocytes.

Grading

The proliferating cells in cases of CAEBVD frequently lack histologic evidence of malignancy and can be polyclonal, oligoclonal, or monoclonal according to the stage of transformation. Ohshima and colleagues proposed a three-tier classification for CAEBVD.[52] Category A1 is polymorphic lymphoproliferative disorder with polyclonal proliferation of EBV-infected T cells or NK cells. Category A2 is polymorphic lymphoproliferative disorder with proliferation of monoclonal T cells or NK cells. Category A3 is monomorphic lymphoproliferative disorder of monoclonal T cells or NK cells. Categories A1, A2, and A3 constitute continuous stages in clonal evolution of CAEBVD. Category A3 corresponds to lymphoma/leukemia, including EBV-positive systemic T-cell lymphoma, extranodal NK/T-cell lymphoma, or aggressive NK-cell leukemia.

Postulated Cell of Origin

The postulated cells of origin are cytotoxic T cells or NK cells.

Prognosis and Predictive Factors

The prognosis of CAEBVD is variable. Some patients experience an indolent clinical course, but many patients die of the disease. The process may evolve from a polyclonal to a monoclonal proliferation of T cells or NK cells and eventually progresses to overt lymphoid malignancy. The main causes of death are hemophagocytic syndrome, multiple organ failure, and T-cell or NK-cell malignancy. The median survival is 78 months. In children, patients with a late onset of CAEBVD (older than 8 years), thrombocytopenia, and T-cell infection have poorer outcomes.[51,64,65] Adult-onset disease has poorer outcome compared with disease of children.[67] The monoclonality of EBV alone does not correlate with an increased risk for mortality.[51] Patients with T-cell CAEBVD often present with high fever, lymphadenopathy, hepatosplenomegaly, and high titers of EBV-specific antibodies, and they experience rapid disease progression. Patients with NK-cell disease, in contrast, often have hypersensitivity to mosquito bites, rash, and high levels of IgE but do not necessarily have elevated EBV-specific antibody titers.[68] The 5-year survival rate of patients with T-cell CAEBVD is 59%, whereas that for NK-cell disease is 87%.[51] Hodgkin lymphoma–like lymphoproliferative disease can occur rarely.[69-71]

Differential Diagnosis

Because the infiltrating cells in CAEBVD are bland looking without overt atypia, it is easy to overlook the diagnosis. In situ hybridization

for EBER is a valuable tool for recognizing the disease in the appropriate clinical setting. Systemic EBV-positive T-cell lymphoma or other EBV-positive T-cell and NK-cell lymphomas must be distinguished from CAEBVD. Systemic EBV-positive T-cell lymphoma is an acute and fulminant disease while CAEBVD is usually a protracted disease in which patients are diagnosed after months and years of EBV-related symptoms. Clinical history is important for the differential diagnosis (**Box 29-4**).

Severe Mosquito Bite Allergy

Synonyms and Related Terms

WHO revised 4th ed.: Severe mosquito bite allergy
WHO proposed 5th ed.: Severe mosquito bite allergy

Definition

Severe mosquito bite allergy is a cutaneous manifestation of EBV-positive NK-cell lymphoproliferative disease characterized by intense local skin reactions, including erythema, bullae, and ulcers healing with scar formation, and accompanied by systemic symptoms such as fever, general malaise, and liver dysfunction after mosquito bites, vaccination, or injection.[5] It has a close association with CAEBVD and aggressive NK-cell leukemia occurring in children (capsule summary in **Box 29-5**).

Epidemiology

Epidemiology of the disease is same as that of other EBV-associated T/NK-cell lymphoproliferative disorder. It is an uncommon disease.

Most cases have been reported from Japan, with a few cases from Taiwan, Korea, and Mexico.

Pathophysiology

Severe mosquito bite allergy is not a simple allergic disease but a cutaneous reaction of underlying EBV-positive NK-cell lymphoproliferation induced by mosquito bites.[72] Peripheral blood analysis of patients shows increased CD4-positive T cells and NK cells. NK cells are infected by monoclonal EBV.[73] CD4-positive T cells are mosquito antigen–specific and proliferate in response to mosquito salivary gland extract.[74] When mosquito antigen–specific CD4-positive cells are cocultured with EBV-carrying NK cells, EBV is activated, and NK cells express EBV lytic cycle antigens. The activation of NK cells latently infected by EBV and the subsequent CTL response seem to play a key role in the pathogenesis of the skin lesions and systemic symptoms of patients with severe mosquito bite allergy.[75,76] EBV-carrying NK cells are clonal and preneoplastic cells, with a risk for subsequent development of overt NK-cell lymphoma/leukemia through the oncogenic influence of latent EBV genes.

Box 29-4 Recommended Tests to Diagnose Chronic Active EBV and Related Diseases

EBER, EBV-encoded RNA; *EBV,* Epstein-Barr virus; *NK,* natural killer.

- In situ hybridization for EBER

- Immunostains for CD3, CD20, CD4, CD8, and CD56
- Double stains for EBER with CD3, CD79a, and CD56 to identify cell lineage of EBV-positive cells
- Immunostains for cytotoxic markers: TIA-1, granzyme B, perforin
- Viral load in peripheral blood
- EBV antibody titers
- EBV terminal repeat analysis (if available)
- TR gene rearrangement

Box 29-5 Major Diagnostic Features of Severe Mosquito Bite Allergy

CAEBVD, Chronic active EBV disease; *EBV,* Epstein-Barr virus; *HVLPD,* hydroa vacciniforme lymphoproliferative disorder; *NK,* natural killer.

Definition

- Cutaneous manifestation of underlying EBV-associated NK-cell lymphoproliferative disorder activated by mosquito bite or injection

Diagnostic Criteria

- Intense local skin symptoms, including erythema, bulla, ulcer, and scar formation, associated with systemic symptoms such as fever, lymphadenopathy, and liver dysfunction after mosquito bites

Clinical Features

- Most patients are in the first two decades of life, with a median age of 6.7 years
- Often high EBV load and NK-cell lymphocytosis
- Variable clinical course; some patients may develop HVLPD, systemic symptoms of CAEBVD, or NK-cell lymphoma/leukemia

Morphology

- Necrosis and ulceration of epidermis, with infiltration of neutrophils and small lymphocytes and fibrinoid necrosis of small blood vessels

Immunophenotype

- Cutaneous infiltration by CD4-positive T cells, CD8-positive T cells, and NK cells expressing cytotoxic molecules
- NK cells containing EBV in peripheral blood

Clinical Features

Most patients are in the first two decades of life, with a median age of 6.7 years.[77] Skin lesions at the site of the mosquito bite typically demonstrate erythema and bullae that subsequently become necrotic with ulceration and eventually heal with scarring (**Fig. 29-3**). Systemic symptoms, including fever and malaise, are common. Hematuria, proteinuria, and bloody stool may be seen, with

laboratory evidence of anemia or hypoproteinemia. After recovery from the general symptoms, patients are symptom free until the next mosquito bite. Vaccination may cause a similar skin reaction at the injection site in some patients.[77] Patients show a high level of serum IgE, a high EBV load in the peripheral blood, and peripheral NK lymphocytosis (80% of patients).[73]

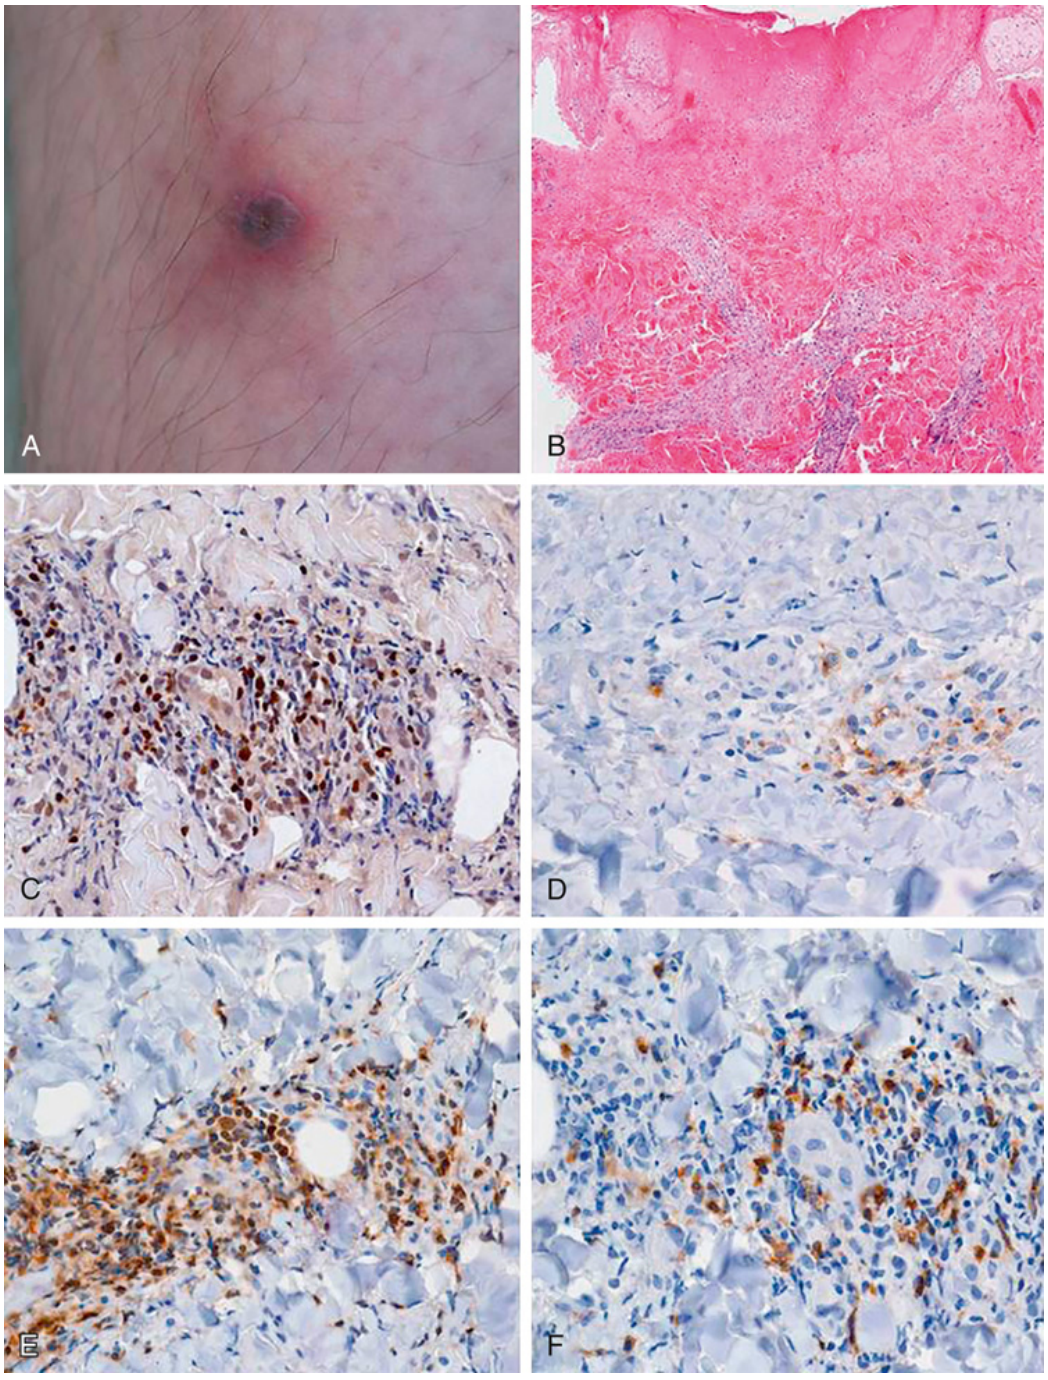

FIGURE 29-3 Severe mosquito bite allergy.A, Skin at the mosquito bite site shows epidermal necrosis and ulceration. **B,** Skin shows necrosis of the epidermis. Blood vessels in the deep dermis exhibit vasculitic changes, with

fibrinoid necrosis and fibrin thrombi. **C,** Many perivascular cells are Epstein-Barr virus–encoded RNA (EBER) positive. **D,** CD56 stains scattered perivascular cells. **E,** Many perivascular cells are CD4 positive. **F,** Some cells are CD8 positive. A, Courtesy Professor H. S. Kim, Chonnam National University.

Patients with CAEBVD can show severe mosquito bite allergy. Complications in patients with severe mosquito bite allergy commonly include NK-cell lymphoma/leukemia and hemophagocytic syndrome.

Morphology

The skin at the mosquito bite site exhibits epidermal necrosis and ulceration. The dermis shows edema and infiltration of polymorphonuclear leukocytes, nuclear debris, and extravasated red blood cells, with fibrinoid necrosis of small blood vessels in the center of the lesion (see **Fig. 29-3**). The infiltrate of small lymphoid cells extends from the dermis to subcutaneous tissue in an angiocentric pattern.

Immunophenotype and Genetics

The infiltrating lymphoid cells in the skin are CD4-positive T cells, CD8-positive T cells, and NK cells that express cytotoxic molecules. EBV-positive cells constitute a minor population, accounting for 3% to 10% of infiltrating lymphocytes. Peripheral blood mononuclear cells in patients with NK lymphocytosis typically contain 30% to 70% of NK cells. Blood NK cells are infected with monoclonal EBV or

occasionally with biclonal EBV, indicating clonal NK cell proliferation.[73]

Postulated Cell of Origin

NK cells are the postulated cells of origin.

Prognosis

The clinical course is variable. Some patients have a prolonged and indolent disease course that may be complicated with CAEBVD or HVLPD. More than half of the patients die. Half the fatal patients die of hemophagocytic syndrome and other 30% to 40% of patients die of NK-cell lymphoma/leukemia.[77,78]

Hydroa Vacciniforme Lymphoproliferative Disorder

Synonyms and Related Terms

WHO revised 4th ed.: Hydroa vacciniform–like lymphoproliferative disorder
WHO proposed 5th ed.: Hydroa vacciniform lymphoproliferative disorder

Definition

Hydroa vacciniforme lymphoproliferative disorder (HVLPD) is a cutaneous EBV-positive lymphoproliferative disease characterized by recurrent papulovesicular and necrotic eruptions of the skin.[5] This condition is divided into two types based on the clinical features, classic and systemic; classic HVLPD is an indolent and self-limited

disease involving only the skin and accounts for the majority of HVLPD occurring in Whites. Systemic HVLPD more commonly affects Asians and Latin Americans and is characterized by skin lesions accompanied by systemic symptoms such as fever, lymphadenopathy, and hepatosplenomegaly during the acute episode (**Table 29-1**).[6,7]

Previously, similar cutaneous lesions corresponding to systemic HVLPD were reported under various names, including hydroa-like cutaneous T-cell lymphoma, edematous scarring vasculitic panniculitis, EBV-associated lymphoproliferative lesions presenting as recurrent necrotic papulovesicles of the face, and angiocentric cutaneous T-cell lymphoma (hydroa-like lymphoma) of childhood.

Epidemiology

Classic HVLPD occurs worldwide, independent of race.[79] Usually the disease is sporadic, but familial cases have been reported in identical twins and siblings.[80,81] Systemic HVLPD has been described mainly in Asia and Latin America, including Japan,[2] Korea,[82,83] Taiwan,[84] China,[85-87] Mexico,[88-89] Peru,[90] and Guatemala,[91] and rarely in Western countries.[10]

Pathophysiology

EBV is found in both classic HVLPD and systemic HVLPD. In classic HVLPD, even though the lesions are confined to the skin, slightly elevated levels of EBV DNA showed in peripheral blood mononuclear cells compared with normal healthy persons, whereas systemic HVLPD has markedly increased levels of EBV DNA and can be associated with other complications.[92]

The patients with HVLPD have increased γδT cells in both peripheral blood and skin, and the γδT-cells in blood contain larger amounts of EBV DNA than non-γδT cells.[93,94] Although the exact mechanism inducing cutaneous homing of these EBV-positive γδT cells is unknown, ultraviolet (UV) is one of the triggering factors. EBV-containing γδT cells homing to the skin admixed with EBV-negative cytotoxic T cells induce an inflammatory reaction and attack the epidermis. The keratinocytes of the epidermis undergo reticular degeneration, leading to the formation of vesicles. An HVLPD skin lesion compared with normal skin showed increased expression of interferon-γ and chemokines that attract T cells and NK cells.[80] Blister fluids from the patients had much higher levels of TNF-α.[95]

* Fever, increased liver enzymes, lymphadenopathy.

Clinical Features

Classic HVLPD

HVLPD usually presents in children younger than 10 years, but occurrence in adults is not uncommon.[83,87,96] The eruption is seasonal, usually occurring in spring or summer. The skin lesions are characterized by recurrent vesicles and crust formation on the face and arms after sun exposure, and they typically heal with

vacciniform scarring (**Fig. 29-4**). Lesions are inducible by sunlight exposure and, less commonly, by repeated exposure to broad-spectrum UVA or, less reliably, UVB irradiation.[97-99]

Systemic HVLPD

Unlike classic HVLPD, the cutaneous lesions can occur in exposed and unexposed sites and are frequently refractory to the wearing of sun protection. Cutaneous lesions might be severe and disfiguring (**Fig. 29-5**). Patients show necrotic papulovesicles or nodules, which can recur for years.[82,88,90,98,100]

Patients present with systemic symptoms during the acute episode such as fever and malaise, which is accompanied by lymphadenopathy, hepatosplenomegaly, increased liver enzymes and lactate dehydrogenase, and large granular lymphocytosis in the peripheral blood.[101,102] A seasonal variation in eruptions is characteristic, being worse in spring and summer and remitting in autumn and winter. During the remission phase, the patients are asymptomatic. Some patients have hypersensitivity to insect or mosquito bites (**Table 29-1**).[88] As the disease progresses, there are more extensive and more severe skin lesions and systemic symptoms. Patients who initially respond to steroids or immunomodulating therapies, however, eventually will require similar treatment as CAEBVD.

Morphology

The characteristic histologic features of HVLPD are epidermal reticular degeneration leading to spongiotic vesiculation. The dermis contains perivascular and periappendageal lymphocytic infiltration. There is no cytologic atypia of infiltrating cells in classic HVLPD. The

histologic changes of systemic HVLPD are similar to those of classic HVLPD, but the dermal infiltrates may be more extensive and deeper, reaching to the subcutaneous tissue. The infiltrates show variable atypia and are often composed of atypical lymphocytes with enlarged and hyperchromatic nuclei, frequently with an angiocentric and periadnexal arrangement and septal or lobular panniculitis. Reactive histiocytes may be admixed.

Immunophenotype and Genetics

In classic HVLPD, the majority of the T-cell population in the skin is composed of EBV-positive CD4-negative or CD8-negative γδT cells and reactive EBV-negative CD4-positive or CD8-positive cytotoxic T cells. NK cells are rare.[93] EBV-positive γδT cells are increased in the peripheral blood.[10,92-94,103] In systemic HVLPD, infiltrating cells in the skin are composed of EBV-positive or EBV-negative T cells that are predominantly CD8-positive CTLs,[90,104] with a minority of CD4-positive cells and some CD56-positive cells.[84,86] A variable number of CD30-positive cells can be seen.[91] EBV-infected cells in peripheral blood are either γδT cells or, less commonly, αβT-cells.[105] TR gene rearrangements of infiltrating cells in the skin may be polyclonal,[98] but more frequently monoclonal.[86]

The number of EBV-positive lymphocytes in the skin varies[98,106] and increases in spring and summer; during periods of remission in autumn and winter, very few EBV-positive cells are present. EBV-containing cells do not express LMP1.

Postulated Cell of Origin

The postulated cells of origin are γδT cells; less commonly, αβT cells; and rarely, NK cells, homing to the skin.

Prognosis

Patients with classic HVLPD show spontaneous remission; some are cured after protection from sunlight, but other patients experience recurrent eruptions that do not spread systemically. Fatalities are uncommon.[79,107] About half the patients with systemic HVLPD can be alive with recurrent disease while another half develop EBV-associated NK/T-cell lymphoma in the skin or other organs 2 to 14 years after onset.[2,4,65,82,86,101,102] Prognosis of classic HVLPD and γδT-cell-dominant systemic HVLPD is favorable, but αβT-cell-dominant systemic HVLPD has a poor prognosis with mortality rates of 11.5 per 100 person-years.[105] Prognosis of patients with adult-onset HVLPD is worse compared with HVLPD of children.[83]

A, Courtesy Dr. J. E. Kwon, Dankook University.

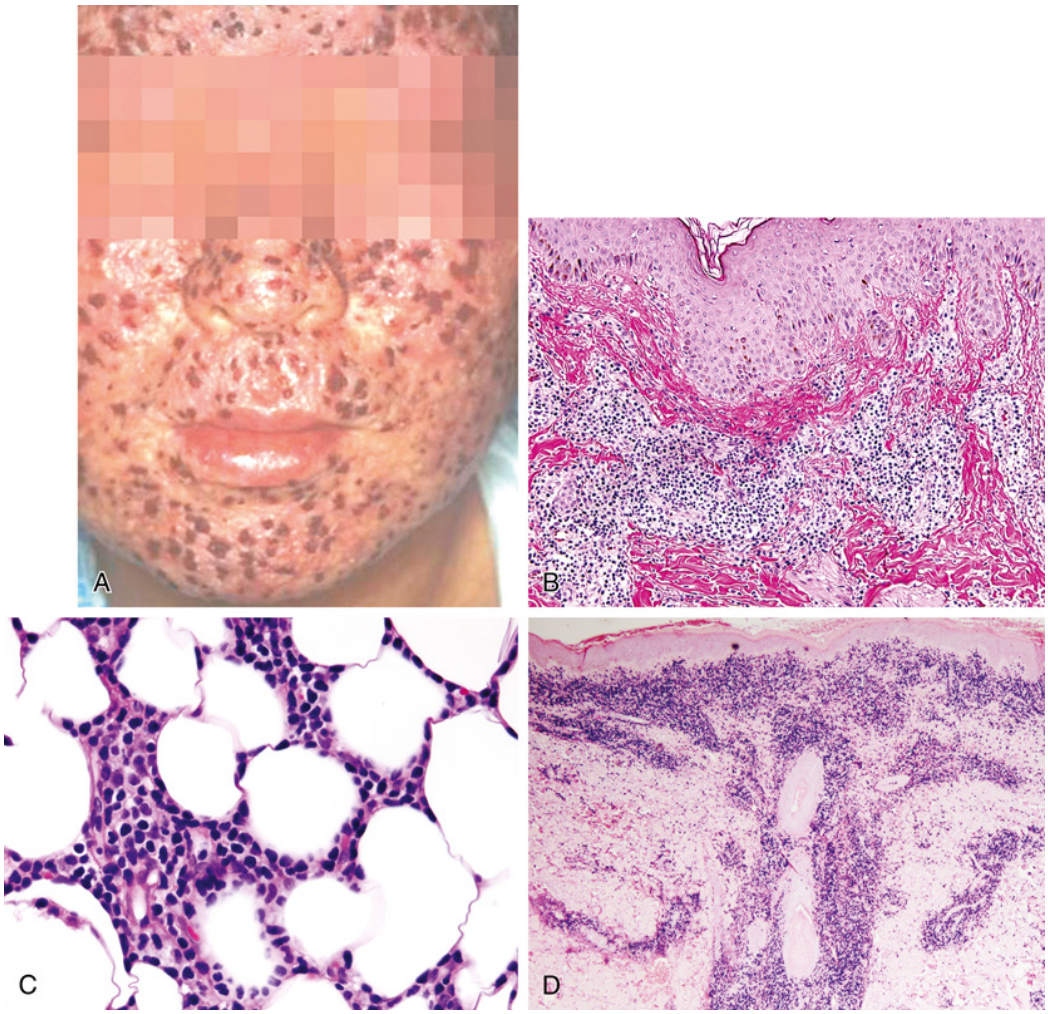

FIGURE 29-5 Systemic hydroa vacciniforme lymphoproliferative disorder.A, This 24-year-old man with recurrent necrotic papulovesicles on the face for 6 years eventually developed systemic Epstein-Barr virus (EBV)–positive T-cell lymphoma. **B,** Small-to-medium-sized lymphoid cells infiltrate the dermis. **C,** Infiltrate extends into subcutaneous tissue. **D,** Nearly all lymphoid cells are EBV-encoded RNA (EBER) positive (EBER in situ

hybridization). A, Courtesy Professor K.H. Cho, Seoul National University.

Differential Diagnosis

The main differential diagnoses for systemic HVLPD are cutaneous NK/T-cell lymphoma and subcutaneous panniculitis-like T-cell lymphoma. Distinguishing extranodal NK/T-cell lymphoma may be problematic in some cases based only on morphology. Clinical information is essential in these cases. Characteristic recurrent papulovesicular skin lesions favor a diagnosis of HVLPD over ENKTL-NT.

Subcutaneous panniculitis-like T-cell lymphoma presents with deep subcutaneous nodules rather than vesiculopapular skin eruptions and is invariably negative for EBV. Primary cutaneous γδT-cell lymphoma may appear clinically similar, and there may be dermal, epidermal, and subcutaneous involvement; the epidermis may be ulcerated. Primary cutaneous γδT-cell lymphoma is also negative for EBV.

Systemic Epstein-Barr Virus–Positive T-Cell Lymphoma of Childhood

Synonyms and Related Terms

WHO revised 4th ed.: Systemic Epstein-Barr virus–positive T-cell lymphoma of childhood

WHO proposed 5th ed.: Systemic Epstein-Barr virus–positive T-cell lymphoma of childhood

Definition

Systemic EBV-positive T-cell lymphoma of childhood and young adults is a rare but life-threatening fulminant illness characterized by a clonal proliferation of EBV-infected T cells, usually CD8 positive, with an activated cytotoxic phenotype. It occurs shortly after primary acute EBV infection or rarely develops in the clinical setting of CAEBVD. It is usually characterized by a rapid clinical progression with organ failure, sepsis, and death. A hemophagocytic syndrome is nearly always present.

Epidemiology

Systemic EBV-positive T-cell lymphoma of childhood, which is most prevalent in Asia and Latin America, is nearly always accompanied by a fulminant hemophagocytic syndrome. It has been described under a variety of names, including *fatal EBV-associated hemophagocytic syndrome,*[108] *fulminant EBV-positive T-cell lymphoma,*[109] *fulminant childhood hemophagocytic syndrome mimicking histiocytic medullary reticulosis,*[110] and *fatal hemophagocytic lymphohistiocytosis*.[111] In recognition of the aggressive clinical behavior, the term *systemic EBV-positive T-cell lymphoma* was adopted in the revised WHO 4th ed., a change from the prior term of *systemic EBV-positive T-cell lymphoproliferative disorder*.[5] The term *systemic EBV-positive T-cell lymphoma of childhood* has been retained in the WHO 5th ed.[7] and in the ICC.[6] Cases have been reported primarily from Taiwan[110,112,113] and Japan,[108,114] with a few cases from Korea[115] and Mexico.[109] The disease occurs most often in young children[116] and young adults.[117]

Systemic EBV-positive T-cell lymphoma developing during the clinical course of CAEBVD has been described mainly in Japan,[1,118] with a few reports from Korea[117] and Western countries.[119] It occurs mainly in teenagers,[1,117] young children, and adults.[1] There is no sex predilection.

Pathophysiology

Hemophagocytic syndrome with a fulminant clinical course is the characteristic clinical picture of systemic EBV-positive T-cell lymphoma of childhood. The infection of T cells by EBV activates T cells to secrete Th1 cytokines such as TNF-α and interferon-γ, which subsequently activate macrophages.[120] EBV LMP1 activates the transcription factors NF-κB and JNK (c-Jun N-terminal kinase); this not only provides the molecular mechanism for LMP1–induced cell proliferation and transformation but also confers resistance to TNF-α–mediated apoptosis via downregulation of TNF-α receptor 1 in the cytokine milieu of hemophagocytic syndrome.[45,121]

Clinical Features

Patients with systemic EBV-positive T-cell lymphoma developing after primary EBV infection usually present with acute onset of fever and general malaise suggestive of an acute viral respiratory illness. Within a period of 1 to 3 weeks, patients develop hepatosplenomegaly, liver dysfunction, pancytopenia, rash, and CNS symptoms. Lymphadenopathy is not common. The disease is usually complicated by hemophagocytic syndrome, coagulopathy, sepsis, and multiorgan failure.[112,122] EBV serology is often abnormal with positive anti-VCA IgG titers but low or absent anti-VCA IgM

antibodies.[48,109] EBV serology in these cases is misleading in that it does not suggest acute primary or active infection, which can delay the diagnosis.

A related disorder but presenting mainly with lymphadenopathy and high lactate dehydrogenase (LDH) levels was reported in children from Peru.[123] In addition to a history of acute onset with fever, weight loss, and hepatosplenomegaly, these children had peripheral, mediastinal, and intraabdominal lymphadenopathy. The disease progressed rapidly, causing the death of the patient in all cases with a median survival of 7 months (1–13 months). This rare presentation is recognized within the spectrum of EBV-positive T-cell lymphoma of childhood.[124]

Systemic EBV-positive T-cell lymphoma arising in patients with a history of CAEBVD develops at a median of 35 months (range, 3–264 months) after the onset of CAEBVD. Before the development of T-cell lymphoma, patients experience intermittent or persistent fever of unknown origin, lymphadenopathy, or liver dysfunction over months or years, or HV-like skin eruptions occurring over months or several years.[1,115] The clinical course in these patients is somewhat more variable than that in patients with primary disease, but most patients eventually die of the disease.

Morphology

Hyperplasia of histiocytes and marked hemophagocytosis with increased numbers of small T lymphocytes are the most striking histologic changes in the bone marrow, spleen, and liver of patients with systemic EBV-positive T-cell lymphoma. The liver exhibits mild to prominent portal and sinusoidal infiltrates of small lymphocytes

with intracellular and intracanalicular cholestasis, steatosis, and focal necrosis, which might be extensive. The spleen shows depleted white pulp and prominent sinusoidal small lymphoid infiltrates. The lymph nodes show preserved architecture with open sinuses. The B-cell areas are depleted, whereas the paracortical areas might be expanded and show a subtle to striking infiltration with relatively homogeneous small, medium, or large lymphocytes with hyperchromatic nuclei and irregular nuclear contours. The more advanced the disease is, the more depleted the lymph nodes look. Epithelioid histiocytes, small granulomas, or necrosis may be present. The degree of cytologic atypia in the EBV-positive lymphocytes is variable, and in many cases the cytology is surprisingly bland (**Fig. 29-6**); however, some cases show atypical lymphoid infiltrates composed of pleomorphic medium-to-large-sized cells and frequent mitosis. In cases presenting predominantly with lymphadenopathy, the lymph node shows partial or total replacement by a diffuse infiltration of atypical cells. Lymph node excision is required for the diagnosis; core needle biopsies, because of the high content in histiocytes and small lymphocytes, might erroneously suggest a reactive condition. The severe clinical manifestations and the presence of hemophagocytosis usually alert one to the serious nature of the lymphoid proliferation.

EBV-positive systemic T-cell lymphomas that develop after a diagnosis of CAEBVD exhibit variable cytologic atypia; however, it is similar to the systemic disease after primary EBV infection.

highlights the interfollicular small lymphoid infiltrate. **E** and **F,** The CD8-positive cells are also TIA1 positive and Epstein-Barr virus (EBV)–encoded RNA (EBER) positive. Note that in the double staining only a proportion of CD8-positive cells *(brown)* is also EBER positive *(black) (inset)*.**G,** TRG gene rearrangement shows a dominant monoclonal peak of 166 base pairs.**H,** The spleen shows a depleted white pulp with expanded red pulp. **I,** The spleen shows striking hemophagocytosis with few lymphoid cells lacking cytologic atypia. **J,** The liver shows a subtle lymphoid infiltrate in the sinusoids with hemophagocytosis. **K,** The lymphoid infiltrate is CD8 positive. **L** and **M,** EBER-positive cells are found both in the spleen and liver.

Immunophenotype and Genetics

The infiltrating cells in primary systemic EBV-positive T-cell lymphoma are predominantly CD8-positive cytotoxic αβT cells.[109,115] They are CD2 positive, CD3 positive, TIA-1 positive, granzyme B positive, and CD56 negative. Cases after CAEBVD show a more heterogeneous phenotype, mostly CD4 positive,[109,118,119] CD4 positive and CD8 positive, or CD8 positive.[1]

EBV is clonal by terminal repeat analysis.[118] In situ hybridization for EBER is positive in the small lymphoid cells that show minimal cytologic atypia, and in the obviously atypical cells. In general, EBER-positive cells are less than the infiltrating CD8-positive cells.

In situ hybridization for EBER and immunohistochemistry (double-staining EBER/CD8 and EBER/CD4) confirm EBV infection in T lymphocytes and the cell derivation. Although EBV-positive T- and NK-cell LPDs carry EBV latency II, LMP1 is often negative by immunohistochemistry and EBNA2 is always negative. Molecular analysis of the TCRG gene shows a monoclonal T-cell proliferation.[109]

Postulated Cell of Origin

The postulated cell of origin in most cases is proliferation of a cytotoxic CD8 lymphocyte with rare cases being of CD4 T-cell origin.

Clinical Course and Prognostic Factors

Patients with systemic EBV-positive T-cell lymphoma after primary EBV infection have a fulminant clinical course, with all patients dying within a few days to months of diagnosis. The rapidly progressive clinical course is similar to that of aggressive NK-cell leukemia. The optimal therapeutic approach for this disease is not currently standardized. Data suggest that HLH-94 protocol has advantages over the HLH-2004 protocol.[125,126] The goal is to stop the hyperinflammatory process characteristic of HLH and continue with the therapy to prepare the patient for allogeneic hematopoietic stem cell transplantation (alloHSCT), which is the only definitive curative therapy for this disease.[125]

Patients with systemic EBV-positive T-cell lymphoma that develops after CAEBVD may have a more prolonged clinical course, but most patients die of the disease within 1 year. The cause of death

is usually disseminated intravascular coagulation, multiorgan failure, and sepsis.[1]

Differential Diagnosis

The differential diagnosis of systemic EBV-positive T-cell lymphoma includes both benign and malignant proliferations of T- and NK-cell derivation. The most challenging differential diagnosis is non-neoplastic EBV-HLH, which shows a relatively favorable outcome with 90% of patients achieving remission with HLH-directed therapy.[42] Importantly, 62% of non-neoplastic EBV-HLH cases show clonal T-cell expansions that do not help in the differential diagnosis.[42,122] Attempts to determine criteria that discern between these two entities have been unsuccessful. Severe hyperbilirubinemia, hyperferritinemia, younger age, higher levels of EBV DNA, and cytologic atypia with extensive architectural effacement are parameters that favor the diagnosis of systemic EBV-positive T-cell lymphoma. The most useful parameter is cytogenetic abnormalities, but these are not always present.[48,49] Systemic EBV-positive T-cell lymphoma, arising either de novo or in the setting of CAEBVD, may show absent or minimal cytologic atypia. Such cases cause diagnostic problems, and the distinction from systemic CAEBVD may be difficult on morphologic grounds alone. In situ hybridization for EBER and clonality analysis does not always help in the differential diagnosis because systemic CAEBVD cases may show a clonal T-cell proliferation.[127,128] The clinical information is necessary to avoid misdiagnosis. The clinical course of systemic CAEBVD is usually protracted, with some patients surviving for many years without disease progression.[51,127]

Aggressive NK-cell leukemia is very similar to systemic EBV-positive T-cell lymphoma arising in young children in terms of the fulminant clinical manifestations, presence of EBV in proliferating cells, and systemic hemophagocytosis. However, aggressive NK-cell leukemia is more common in adults (typically young adults), and the tumor cells express NK-cell markers, including CD56, and do not show clonal T-cell receptor gene rearrangement.[129,130]

Extranodal NK/T-Cell Lymphoma, Nasal Type

Synonyms and Related Terms

WHO revised 4th ed.: Extranodal NK/T cell lymphoma, nasal-type

WHO proposed 5th ed.: Extranodal NK/T cell lymphoma

Definition

Extranodal NK/T-cell lymphoma, nasal type (ENKTL-NT), is an extranodal lymphoma of NK- or T-cell lineage, characterized by a broad cytologic spectrum, prominent necrosis, angiocentric-angiodestructive growth, cytotoxic phenotype, and association with EBV (capsule summary in **Box 29-6**).[131] The qualifier "nasal-type" is retained in the ICC to stress the fact that cases presenting outside the nasal region have the same morphologic features; namely, a tumor characterized by vascular damage and destruction, prominent necrosis, cytotoxic phenotype, and association with EBV.[6,9,11,132] Cases with primary nodal presentation are classified as *primary nodal EBV-positive T/NK-cell lymphoma*.[6]

Epidemiology

ENKTL-NT occurs with a higher prevalence among Asians, Mexicans, and South Americans, accounting for 6% to 13% of all non-Hodgkin lymphomas in these populations, compared with less than 1.5% in Western populations.[133-137] Among mature T-cell and NK-cell lymphomas, it constitutes 22.4% of cases in Asia (up to 44%, excluding Japan), compared with 4.3% to 5.1% in North America and Europe.[138] It is the commonest type of primary nasal lymphoma in Asian and Southern American populations.[134,139-142]

This tumor occurs almost exclusively in adults, with a median age of 44 to 58 years. The male-to-female ratio is 2–3:1.[139,143-148]

Etiology

EBV plays an important role in the genesis of ENKTL-NT and EBV is, by definition, present.[11] Cases that are EBV negative are excluded from this category.[149] The EBV exists in a clonal episomal form in the tumor cells, and usually shows type II latency pattern (EBNA1 positive, LMP1 positive, EBNA2 negative) (**Box 29-6**).[145,150,151] It is usually of subtype A, with a high frequency of 30-base pair deletion of the *LMP1* gene.[145,150,151]

Racial factors appear to be significant as evidenced by marked differences in the incidence of ENKTL-NT in different populations. Genome-wide association studies have identified susceptibility loci at HLA-DPB1 (6p21.32), HLA-DRB1 (6p21.32), and IL18RAP (2q12.1).[152,153]

Some examples occur in organ transplant recipients, suggesting that iatrogenic immunosuppression may facilitate the development of this lymphoma type.[154,155] Exposure to pesticides and chemical

solvents has been found to be a risk factor for development of ENKTL-NT.[156] There are isolated reports of occurrence of extranodal NK/T-cell lymphoma in breast implant,[157] by transplacental transmission,[158] and in familial settings, possibly related to pesticide exposure.[159]

Box 29-6 Major Diagnostic Features of Extranodal NK/T-Cell Lymphoma, Nasal Type

Clinical Features and Behavior

- More prevalent among Asians and South Americans
- Age: Adults (median age 44–58 years)
- Sex: Male > Female
- Predilection sites: nasal cavity, other regions of the upper aerodigestive tract, skin, gastrointestinal tract, testis, soft tissue
- Presentation: Necrotizing, ulcerative, or mass lesion
- Stage: Usually early stage for nasal cases (~70% stage I/II) and high stage for extranasal cases (~80% stage III/IV)
- An aggressive tumor with frequent systemic dissemination in a high proportion of cases and general resistance to conventional chemotherapeutic agents

Morphology

- Usually prominent ulceration and tissue necrosis
- Commonly angiocentric and angioinvasive growth

- Neoplastic cells variable in appearance (small-sized, medium-sized, or large-sized cells, or mixed), and often admixed with apoptotic bodies and inflammatory cells. Cases predominated by small cells are difficult to distinguish from reactive lymphoid infiltrate—immunostains (such as CD56, TIA1) and in situ hybridization for EBER are frequently required to support a diagnosis of lymphoma.

Immunophenotype and Genotype

- Majority of cases: $CD3\varepsilon^+$, surface $CD3^-$, $CD56^+$, cytotoxic molecules+, $EBER^+$
- $CD56^-$ subset: $CD3\varepsilon^+$, surface $CD3^{-/+}$, $CD56^-$, cytotoxic molecules+, $EBER^+$
- TR gene usually germline

ENKTL-NT arising in children or young adults can be preceded by CAEBVD of T or NK type, including severe mosquito bite allergy.[52,160]

Clinical Features

Nasal NK/T-cell lymphomas arise in the nasal cavity, nasopharynx, or upper aerodigestive tract, causing progressive destructive and ulcerative lesions (so-called “midfacial destructive disease”) with bleeding and discharge or obstructive symptoms caused by mass lesions. The tumor frequently spreads to the adjacent anatomic structures such as the paranasal sinuses, orbit, oral cavity, palate, and oropharynx, and is typically associated with bone erosion.[161,162] Most patients have early stage disease (~70% stage I and II) at

presentation.[139,143,144] Bone marrow involvement occurs in 10% to 16% of patients.[146,163]

Extranasal NK/T-Cell Lymphoma

Extranasal (non-nasal) NK/T-cell lymphoma is much less common than nasal NK/T-cell lymphoma.[145,164] The most frequently involved sites are the skin, gastrointestinal tract, testis, and soft tissues, which are the same sites that nasal NK/T-cell lymphoma tends to disseminate to during the course of the disease.[143,144,165-170]

The patients often present at high stage (stage III or IV), with involvement of multiple anatomic sites.[143,147,166] Systemic symptoms such as fever, malaise, and weight loss may occur. Serum lactate dehydrogenase is often raised, and anemia is not uncommon.[143] The performance status is often poor.[143,166] The skin lesions take the form of multiple nodules, which commonly ulcerate with a necrotic center. They most often occur in the limbs.[167] Intestinal lesions commonly manifest as perforation or gastrointestinal bleeding, and sepsis is a common complication.[170,171] Involvement of the testis or soft tissue usually manifests as mass lesion.

Rare cases of intravascular NK/T-cell lymphoma have been reported, usually involving skin and CNS.[172-177] Almost all cases harbor EBV, and the disease is highly aggressive. It is currently unclear whether this represents a distinct entity or an unusual subtype of extranodal NK/T-cell lymphoma or aggressive NK-cell leukemia.

Morphology

General Features

The affected tissue is frequently but not invariably ulcerated and necrotic (**Fig. 29-7**). It is diffusely infiltrated by closely packed lymphoma cells (**Fig. 29-7B**).[132] The cytologic composition varies from case to case, ranging from predominantly small-sized cells, medium-sized cells, or large-sized cells to a mixture, with medium-sized cells being the most common. The small cells usually have irregularly folded, angulated, or serpentine-shaped nuclei with dense chromatin, inconspicuous nucleoli, and a narrow-to-moderate rim of pale cytoplasm (**Fig. 29-8**), but they can sometimes resemble small lymphocytes (**Fig. 29-8C**).[178,179] The medium-sized cells possess round or irregularly folded nuclei, granular chromatin, small nucleoli, and a moderate amount of pale-to-clear cytoplasm (**Fig. 29-9**). The large cells have round or folded nuclei, vesicular or granular chromatin, and distinct nucleoli (**Fig. 29-10**), and occasionally appear anaplastic. Azurophilic cytoplasmic granules are often detectable in Giemsa-stained cytologic preparations (**Fig. 29-11**), while cytoplasmic granules are usually not seen in H&E-stained histologic sections. Mitotic figures are readily found, even in small-cell-predominant lesions. There are frequently interspersed apoptotic bodies, lying free or ingested by macrophages (**Fig. 29-12A**). Zonal geographic necrosis is common, comprising ghost shadows of necrotic cells and karyorrhectic debris admixed with fibrinoid exudate and blood (**Fig. 29-12B**).

Angiocentric growth, defined as accentuation of tumor cells around blood vessels, with infiltration and destruction of the walls (**Fig. 29-13**), is reported in 25% to 100% of cases.[144,145,147] The lower figure probably results from limited sampling in small

biopsies. Even in the absence of lymphoma infiltration, the blood vessels commonly show fibrinoid necrosis, fragmentation of the elastic lamina, and thrombosis (**Fig. 29-13C**). The necrosis and vascular damage are reminiscent of those observed in other EBV-associated lymphoproliferative disorders such as lymphomatoid granulomatosis; these features have been postulated to be mediated by EBV-induced monokines and chemokines such as Mig and IP-10.[180]

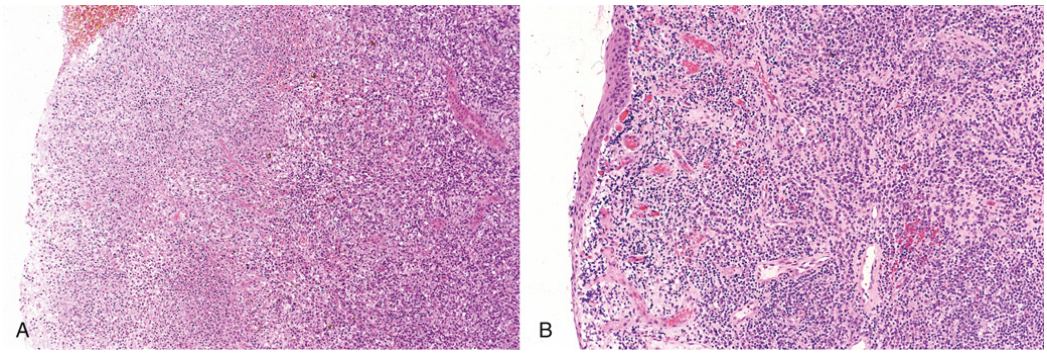

FIGURE 29-7 Nasal NK/T-cell lymphoma.A, The mucosa shows extensive ulceration and necrosis *(left field)*. **B,** In this example, the mucosa is intact and densely infiltrated by lymphoma cells.

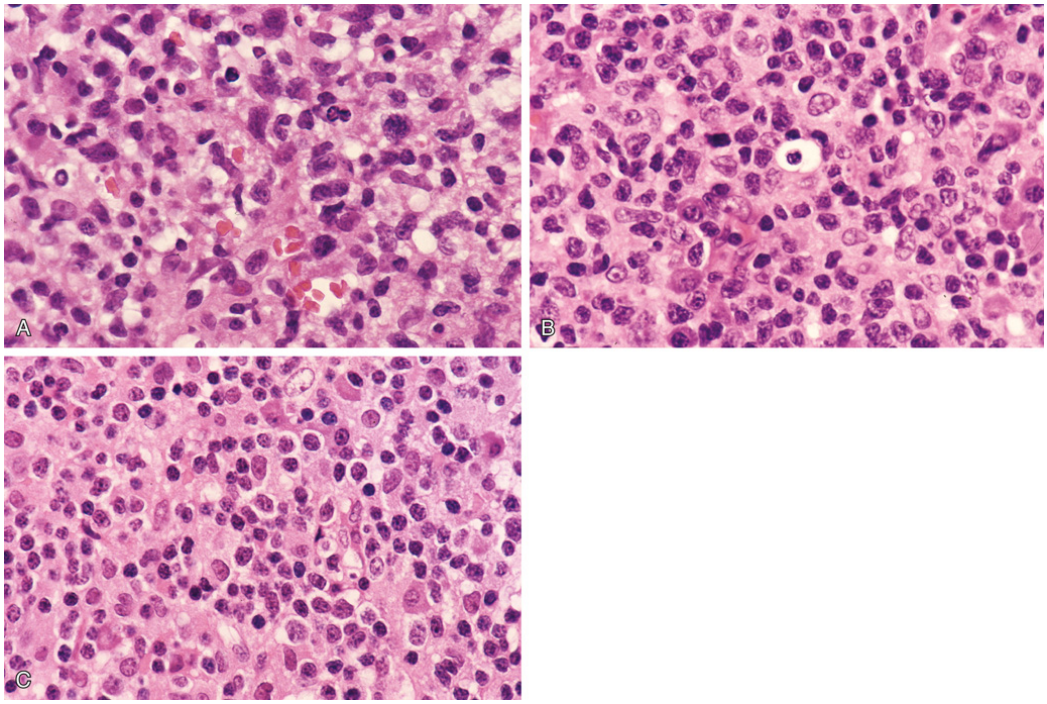

FIGURE 29-8 NK/T-cell lymphoma comprising small cells.A, Most lymphoma cells are small and show irregular nuclear foldings and granular chromatin. Many cells have elongated and angulated nuclei. **B,** In this example, the small lymphoid cells show irregular nuclear foldings, but most maintain a rather rounded overall contour. **C,** The lymphoma cells resemble normal small lymphocytes in this example.

In some cases, the background is rich in inflammatory cells, including small lymphocytes, plasma cells, histiocytes, and neutrophils, overshadowing the lymphoma cells (**Fig. 29-14**). Eosinophils are, however, uncommon.

Site-Specific Features

In the upper aerodigestive tract, the mucosal glands are often pushed apart and destroyed by the lymphoma cells. Some mucosal glands can exhibit cytoplasmic clearing as a form of cell injury (**Fig. 29-15**). The surface epithelium can be infiltrated by lymphoma cells, or may undergo squamous metaplasia and florid pseudoepitheliomatous hyperplasia, with irregular downgrowth and nuclear atypia, mimicking squamous cell carcinoma (**Fig. 29-16**).[132,181]

In the skin, there is a perivascular, periadnexal, or diffuse infiltrate of lymphoma cells in the mid and deep dermis, with or without subcutaneous involvement (**Fig. 29-17**). Coagulative necrosis and ulceration are common. Invasion of the epithelial structures is more frequently seen in nasal NK/T-cell lymphoma disseminating to skin than primary cutaneous NK/T-cell lymphoma.[182,183] In the subcutaneous tissue, the lymphoma cells percolate among the adipocytes, producing a panniculitis-like picture (**Fig. 29-18**). The lymphoma cells can palisade around fat vacuoles, and fat necrosis is common.[167]

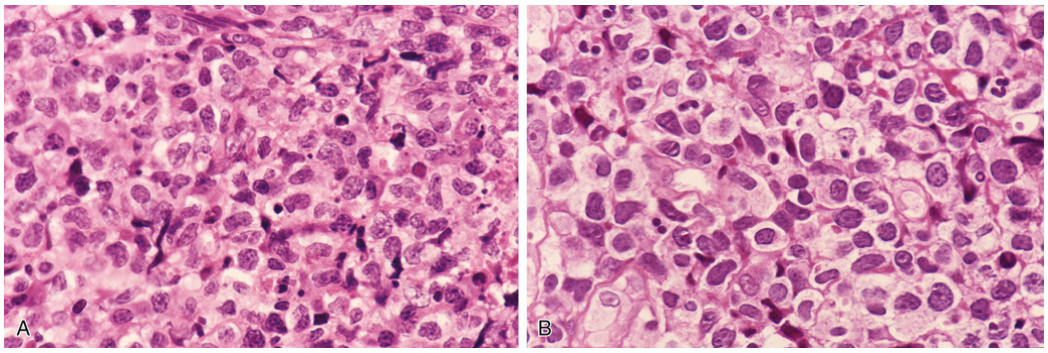

FIGURE 29-9 NK/T-cell lymphoma comprising medium-sized cells.**A,** The medium-sized cells show irregular nuclear foldings and scanty cytoplasm. Note the admixed apoptotic bodies. **B,** In this example, the medium-sized lymphoma cells possess a moderate amount of clear cytoplasm.

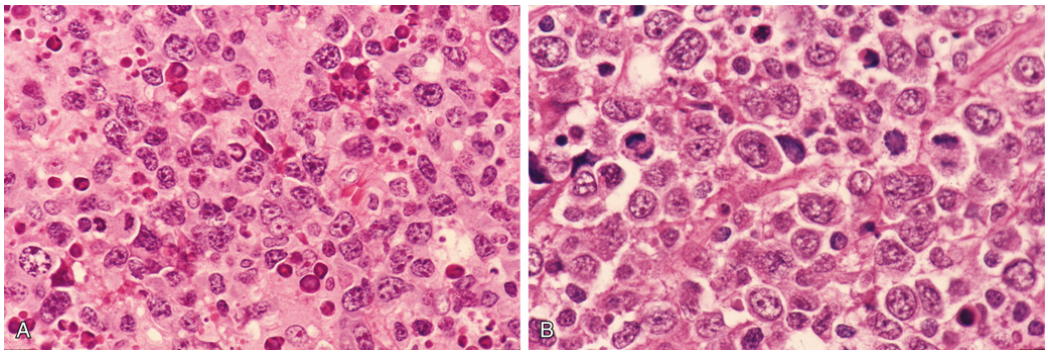

FIGURE 29-10 NK/T-cell lymphoma comprising large cells.A, The large cells show distinct nucleoli, and there are many intermingled apoptotic bodies. **B,** The cells are even larger in this example. Distinction from a diffuse large B-cell lymphoma cannot be made on morphologic grounds alone.

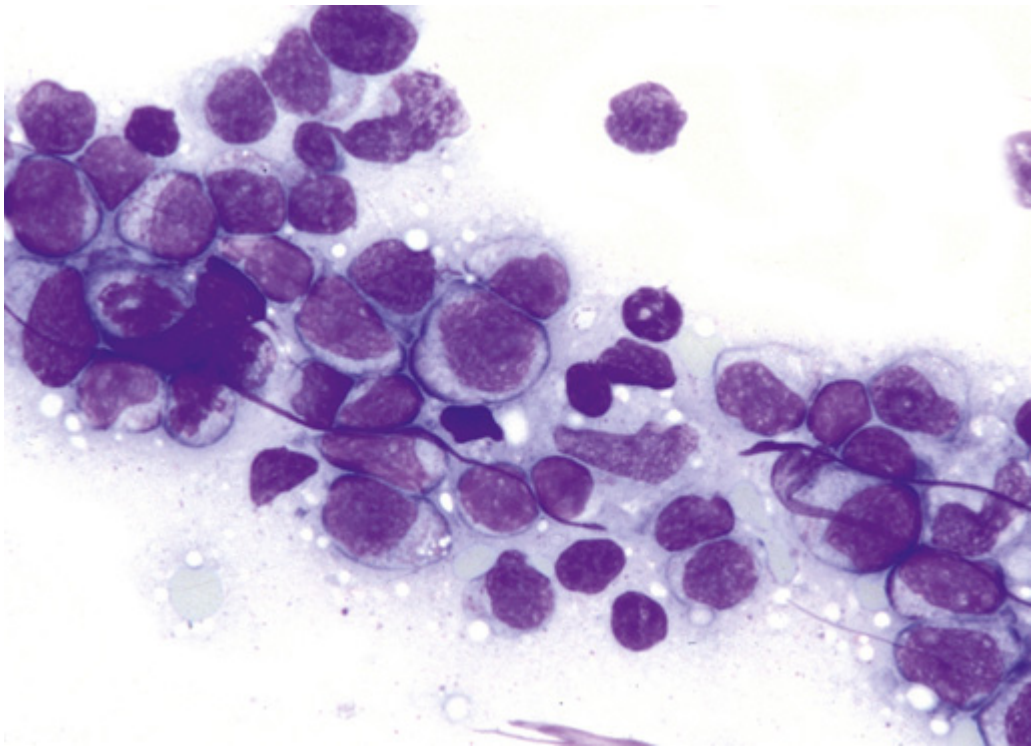

FIGURE 29-11 Nasal NK/T-cell lymphoma.A Giemsa-stained touch preparation reveals medium-sized cells with pale cytoplasm. Some cells contain fine azurophilic granules (where cytotoxic molecules are stored).

In the gastrointestinal tract, there is usually transmural lymphoma infiltration. Extensive coagulative necrosis, deep ulcers, and perforation are common (**Fig. 29-19**).[165,170,171,184]

In the testis, there is infiltration of the interstitium by dense sheets of lymphoma cells, often accompanied by angiodestruction and necrosis.[169] The seminiferous tubules are lost, atrophic, or infiltrated by lymphoma cells (**Fig. 29-20**).

In the soft tissues, there is a permeative growth, prominent destruction of skeletal muscle fibers, and invasion of the nerves (**Fig. 29-21**). The muscle fibers may show flocculent necrosis, invasion of

the cytoplasm by lymphoma cells, or dropout of individual cells, leaving behind empty spaces.

Grading

Cytologic grading of NK/T-cell lymphoma is optional, because of lack of definite prognostic significance.[139,146,147,185] The International Peripheral T-Cell Lymphoma Project reports the presence of >40% transformed cells to predict a worse overall survival in the nasal cases, but not the extranasal cases.[143]

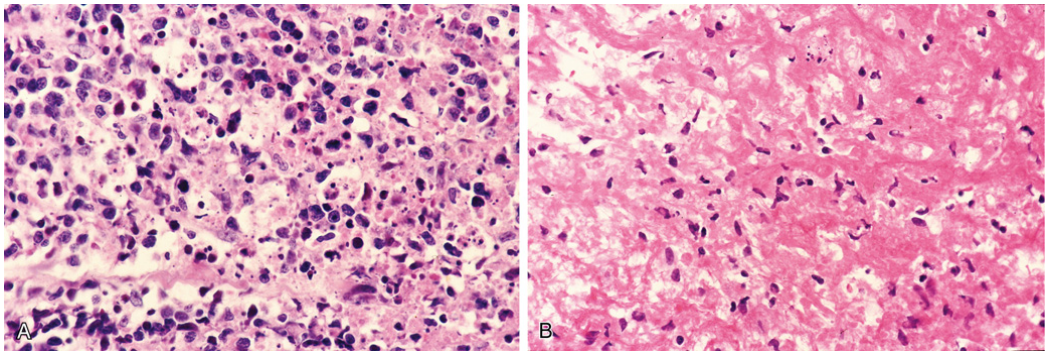

FIGURE 29-12 Extranodal NK/T-cell lymphoma.A, Numerous apoptotic bodies (karyorrhectic debris) are found among the lymphoma cells. **B,** Extensive necrosis with fibrin deposition is a common finding.

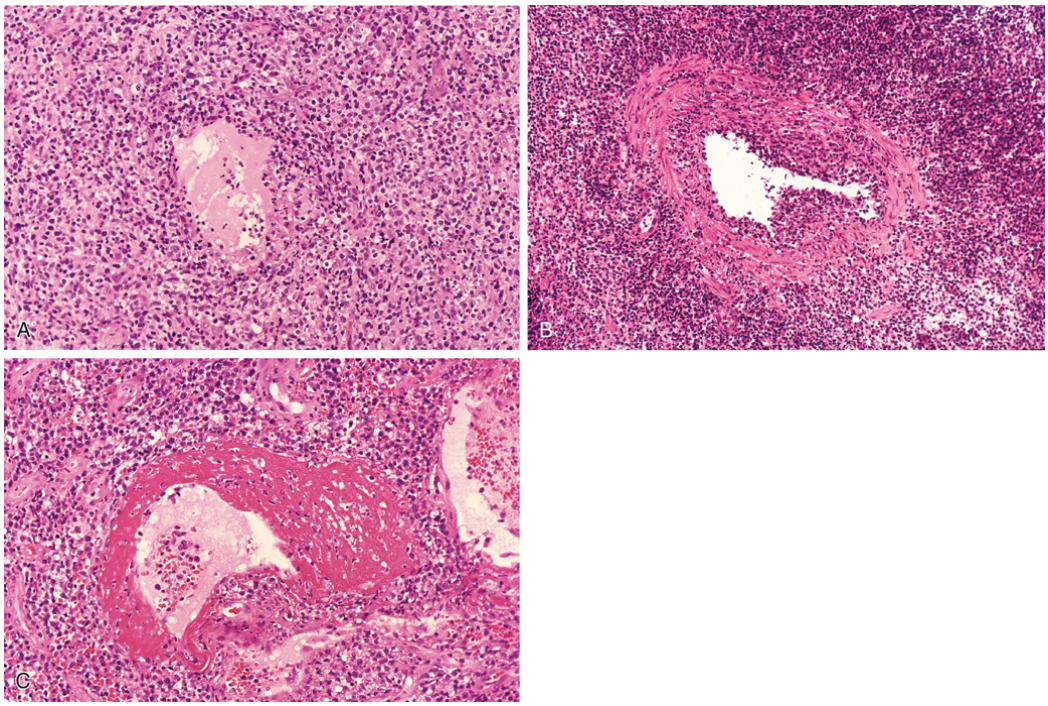

FIGURE 29-13 Vascular changes in nasal NK/T-cell lymphoma.A, The blood vessel wall is swarmed with lymphoma cells. This qualifies for angiocentric growth because the tumor cell density is much higher in the vessel wall compared with the surrounding involved tissue. **B,** Not only is there concentration of lymphoma cells around and in the wall of this blood vessel, but there is also infiltration of the intima. This qualifies for angiocentric growth. **C,** There is deposition of fibrinoid material in the blood vessel wall.

Immunophenotype

The prototypic immunophenotype of NK/T-cell lymphoma is: $CD2^+$, surface $CD3^-$, cytoplasmic $CD3\varepsilon^+$, $CD5^-$, and $CD56^+$, although

occasional cases may show minor deviations, such as lack of cytoplasmic CD3ε or CD56 expression (**Table 29-2**, **Box 29-6**) (**Fig. 29-22**).[143-147,149] CD43 and CD45RO are commonly positive, and CD7 is variably expressed. CD4 and CD8 are uncommonly expressed (**Table 29-2**).[143,186,187] A small percentage of cases express αβ-TCR or γδ-TCR.[144,147,188] Rare cases can exhibit aberrant expression of CD20.[189,190]

The only NK marker that is consistently expressed is CD56, while CD16 and CD57 are usually negative (**Table 29-2**) (**Fig. 29-22C**). Although the expression of CD56 is usually consistent in the various sites of involvement and in relapses, a CD56-positive tumor may relapse as a CD56-negative tumor, or vice versa. Cytotoxic molecules such as TIA-1, granzyme B, and perforin are usually positive and they may mediate the tissue injury and cell death commonly observed in this lymphoma type.[191]

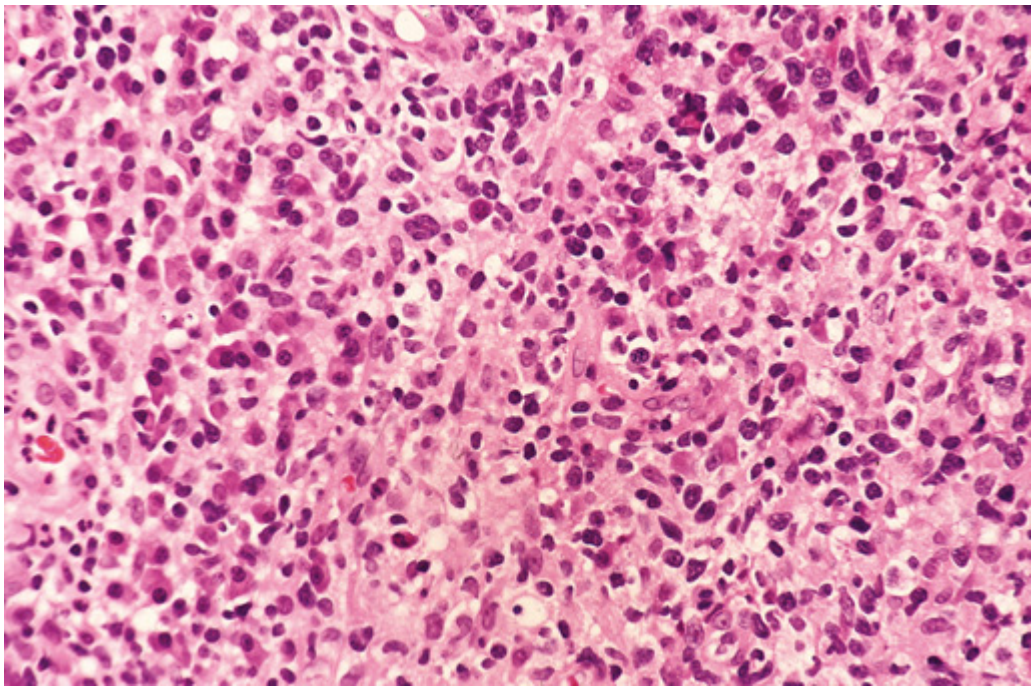

FIGURE 29-14 Nasal NK/T-cell lymphoma.Not uncommonly, the cellular infiltrate is polymorphous, with many intermingled acute and chronic inflammatory cells.

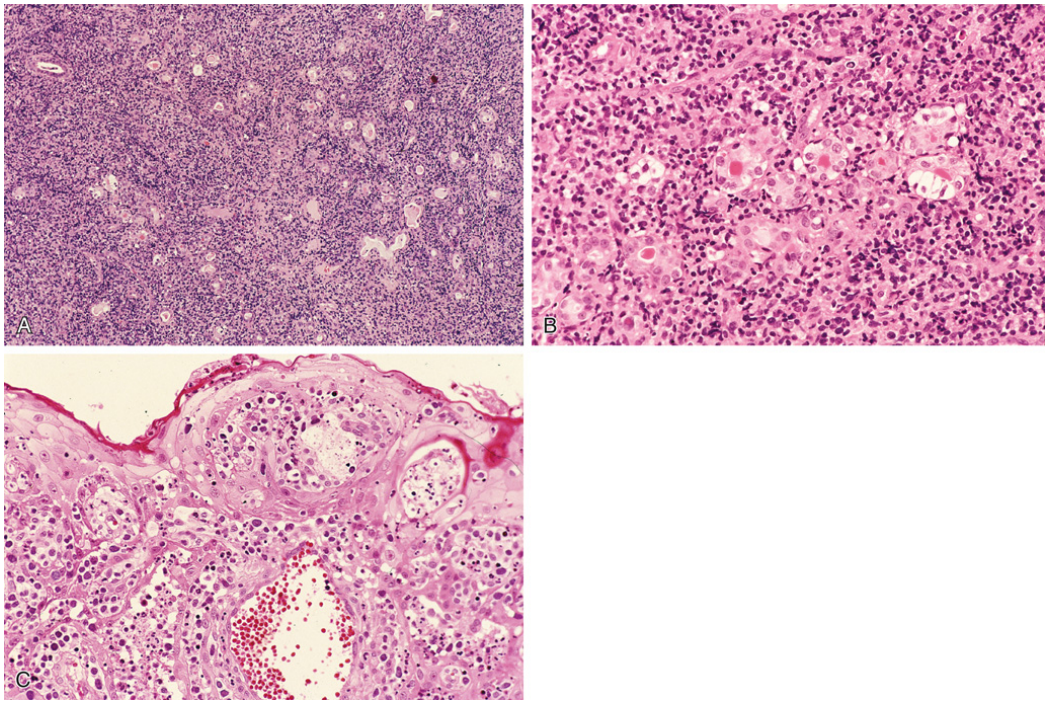

FIGURE 29-15 Nasal NK/T-cell lymphoma.A, Typically the nasal mucosa is expanded by a dense lymphoid infiltrate. The mucosal glands, which normally occur as discrete lobules, are pushed apart by the lymphomatous infiltrate. **B,** The interstitial lymphomatous infiltrate causes separation of the mucosal glands, which commonly exhibit clear cell change. **C,** In this example, the surface epithelium shows squamous metaplasia and infiltration by lymphoma cells.

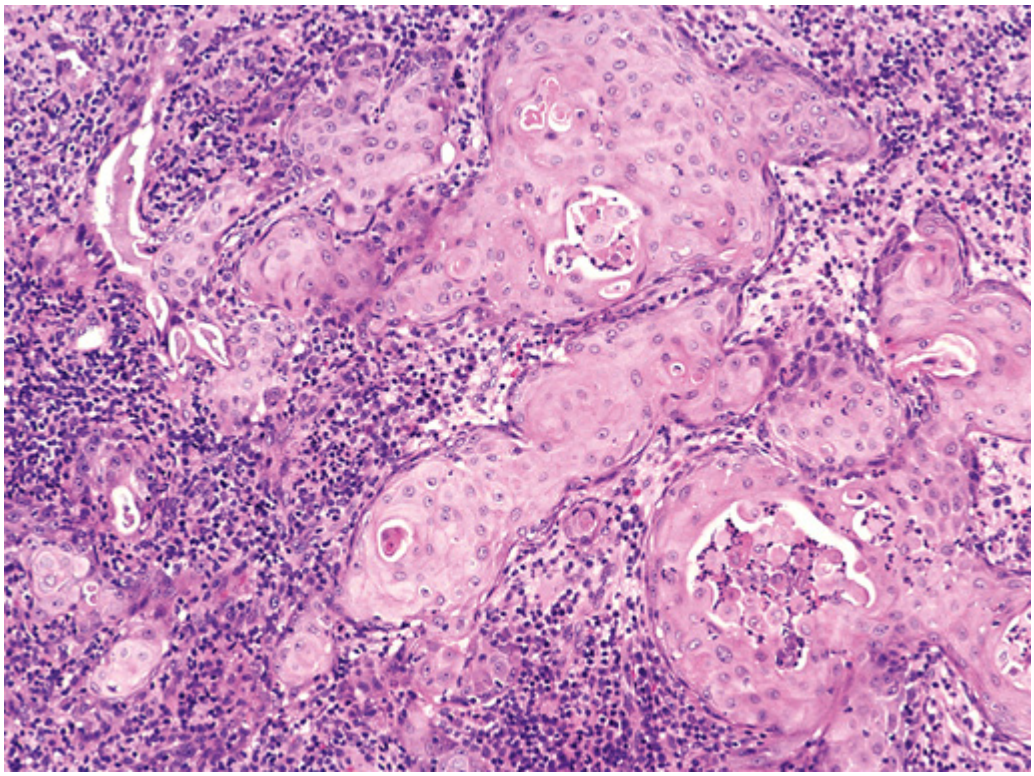

FIGURE 29-16 Nasal NK/T-cell lymphoma with florid pseudoepitheliomatous hyperplasia, mimicking squamous cell carcinoma.

Similar to normal NK cells, both Fas (CD95) and Fas ligand (CD178) are frequently expressed,[192,193] and the Fas-Fas ligand system has been postulated to play a role in tumor apoptosis and vascular injury. A proportion of cases express HLA-DR (~40%) and CD25 (15-35%).[147] CD30 is positive in 20% to 57% of cases, especially in those rich in large cells, but the staining is usually focal and not intense,[145,146,149,194,195] and the prognostic significance is controversial.[194-196] Nuclear expression of MATK is common.[147,197]

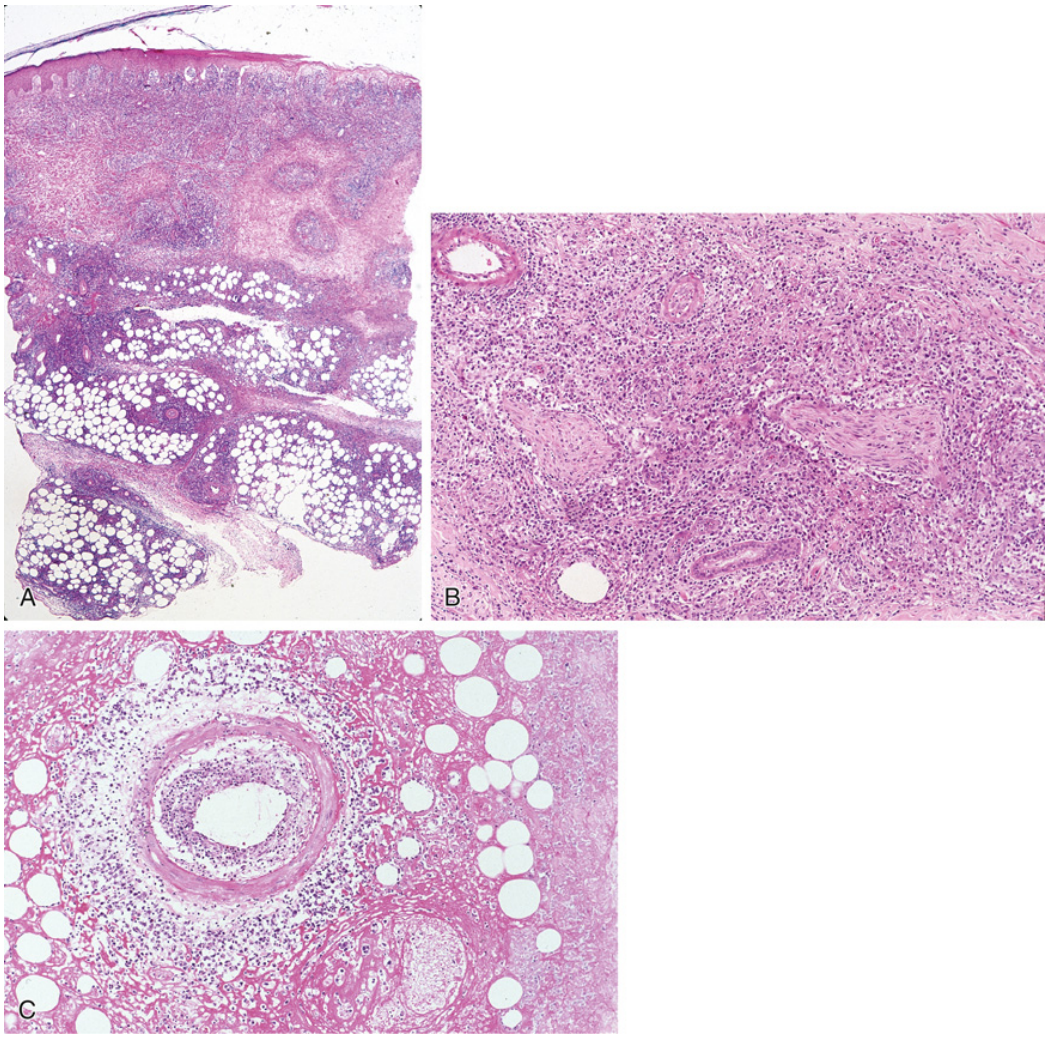

FIGURE 29-17 Cutaneous NK/T-cell lymphoma.A, Both the dermis and subcutaneous tissue are involved, and there are characteristically necrotic foci *(right upper field)*. **B,** The dermis is heavily infiltrated by lymphoma cells, and nerves are also invaded. **C,** The subcutaneous tissue shows prominent necrosis and angiocentric-angiodestructive growth.

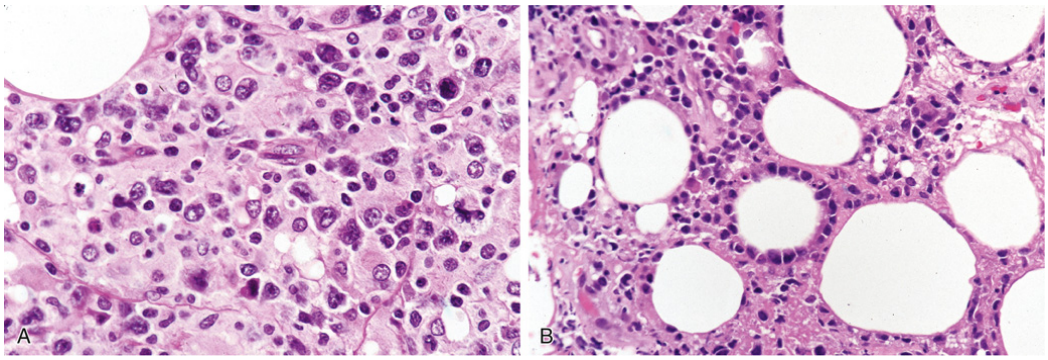

FIGURE 29-18 Cutaneous NK/T-cell lymphoma with involvement of subcutaneous tissue.A, The subcutaneous tissue shows infiltration by a mixture of atypical small-sized, medium-sized and large-sized lymphoid cells. **B,** The lacelike infiltrate and rimming of fat vacuoles by lymphoma cells simulate subcutaneous panniculitis-like T-cell lymphoma.

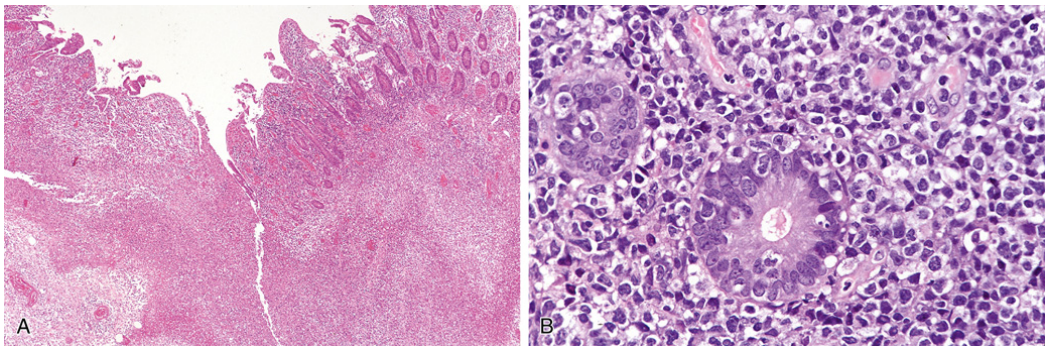

FIGURE 29-19 Primary NK/T-cell lymphoma of the gastrointestinal tract.A, The ileum shows infiltration by lymphoma, necrosis, deep ulceration, and perforation. **B,** The rectal mucosa shows dense interstitial infiltration by lymphoma cells with clear cytoplasm. There is also invasion of the crypt epithelium.

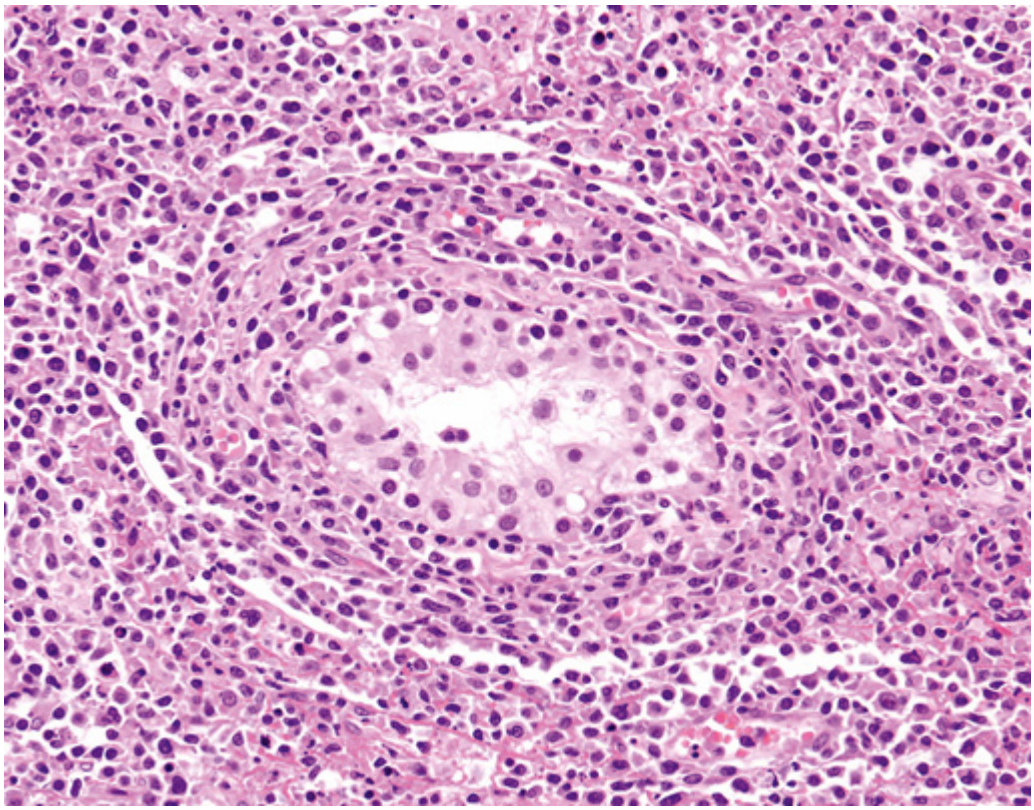

FIGURE 29-20 Primary testicular NK/T-cell lymphoma.The dense lymphomatous infiltration is accompanied by a striking loss of seminiferous tubules. The tubule in the *center field* shows multilayering of the basement membrane caused by infiltration by lymphoma cells.

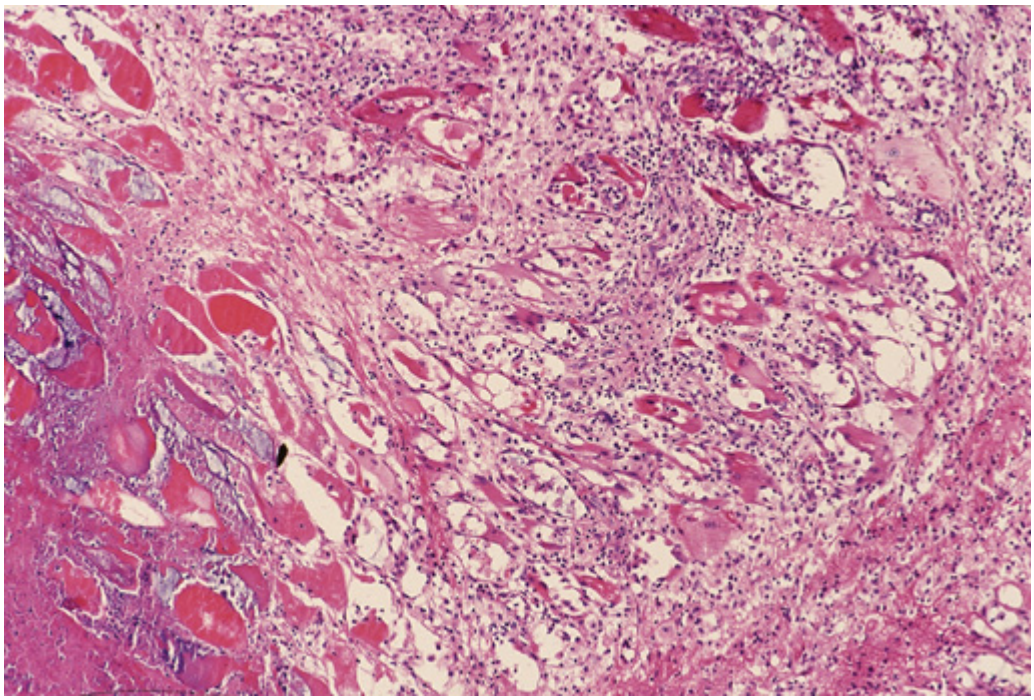

FIGURE 29-21 Primary soft tissue NK/T-cell lymphoma.There is interstitial infiltration of lymphoma, accompanied by prominent necrosis and destruction of skeletal muscle fibers.

‡ References 186,216,268,271,272,277.

§ CD5 is usually negative for those of NK lineage, but may be expressed in those of cytotoxic T lineage.

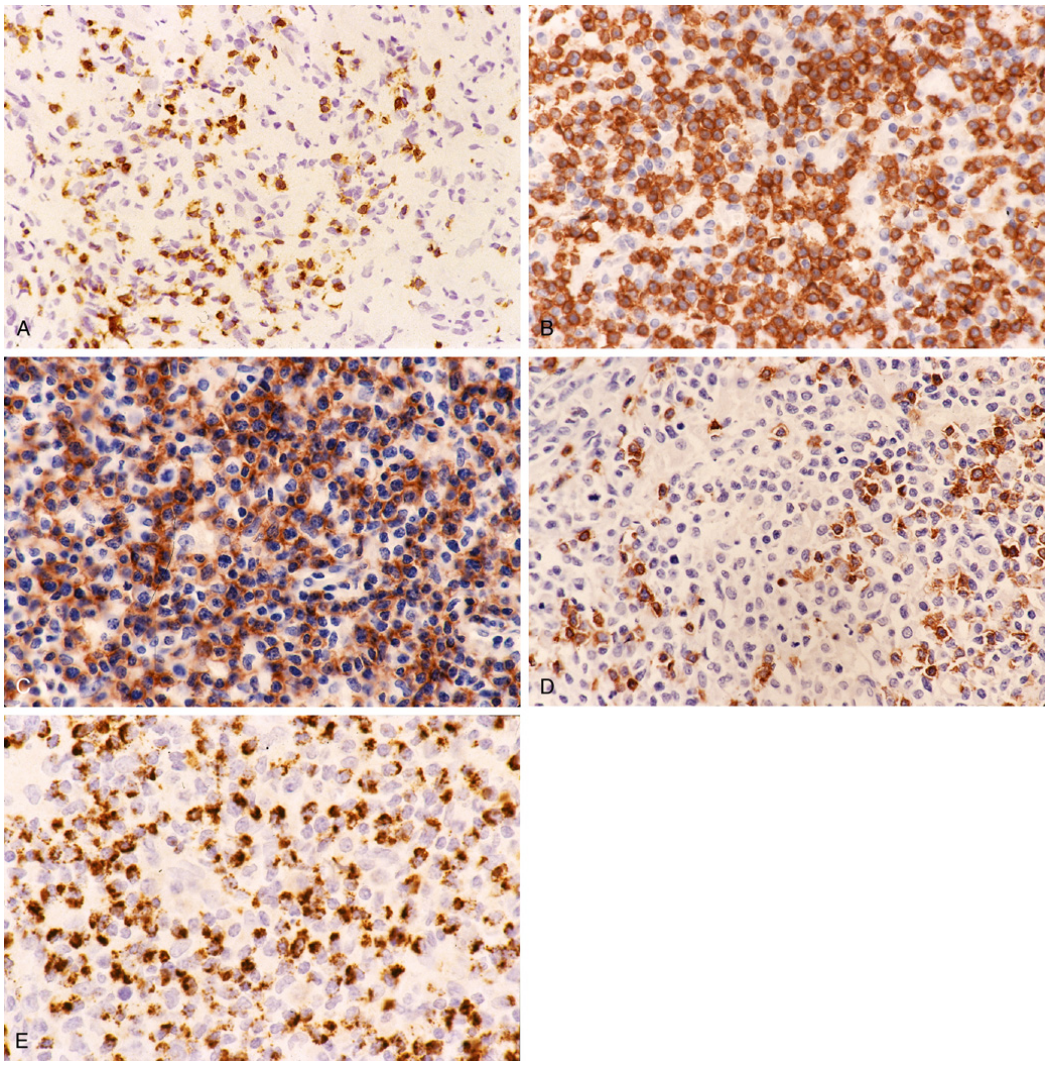

FIGURE 29-22 Immunohistochemistry of nasal NK/T-cell lymphoma.A, Immunostaining for surface CD3 on frozen section using the antibody Leu4 highlights scattered small lymphocytes, while the larger cells are negative. **B,** On the other hand, immunostaining for cytoplasmic CD3ε on paraffin section shows diffuse dense sheets of positive cells. **C,** CD56 is positive. **D,** CD5 is negative. The scattered positive cells are admixed

reactive T cells. **E,** Numerous cells show granular staining for the cytotoxic marker TIA-1.

The proliferative fraction as demonstrated by Ki67 immunostaining is usually high (>50%), even for small-cell-predominant lesions.[144] Some studies suggest that a high Ki67 index (using cutoffs ranging from 60%–70%) is associated with a worse prognosis, and one study reports a Ki67 index of >50% to predict worse overall survival for nasal but not extranasal cases.[146,198-200]

Most NK/T-cell lymphomas express the NK-cell receptor CD94/NGK2, but only some express KIRs.[186,187] NK-cell receptors are not specific for NK/T-cell lymphomas, but are also expressed by some cytotoxic T-cell lymphomas and hepatosplenic T-cell lymphomas. However, demonstration of a skewed NK-cell repertoire by flow cytometry using antibodies against KIRs, CD94, and NKG2A may imply a monoclonal NK-cell proliferation.[201]

CD56-Negative Subset

Nasal lymphomas that are CD56 negative but demonstrate a CD3ε-positive, cytotoxic molecule–positive, EBV-positive phenotype are also included within the category of nasal NK/T-cell lymphoma.[132] Some of them are probably NK-cell lymphomas that have lost CD56 expression, while others are cytotoxic T-cell lymphomas.[193,202] The clinical features and morphology of the CD56-negative group are indistinguishable from the CD56-positive group.[143] Those nasal lymphomas that show a CD3ε-positive, CD56-negative, cytotoxic molecule–negative, EBV-negative phenotype should be diagnosed instead as peripheral T-cell lymphoma, not otherwise specified (NOS).

Genetics and Molecular Findings

The TR and IG genes are in germline configuration in most cases. Clonal rearrangements of TR genes are reported in 10% to 40% of cases; the positive cases presumably represent neoplasms of cytotoxic T cells rather than NK cells.[141,143-147]

There is, by definition, consistent association with EBV, and in situ hybridization for EBER typically labels virtually all tumor cells (**Fig. 29-23**).[149] Demonstration of EBV may aid in diagnosis, because the many types of peripheral T-cell lymphomas that show morphologic and immunophenotypic overlap with NK/T-cell lymphoma are almost always negative for EBV.[203] Circulating whole blood or plasma EBV DNA level is often elevated, and a high titer is correlated with extensive disease, unfavorable response to treatment, and poor survival.[204-206] Decline of EBV DNA to undetectable level after treatment is associated with a favorable prognosis.[205,207]

The gene-expression profiles of all extranodal NK/T-cell lymphomas cluster together irrespective of NK- or cytotoxic T-cell lineage, supporting the current classification to include tumors of these two lineages in the same lymphoma category.[208,209] Interestingly, non-hepatosplenic γδT-cell lymphoma also shows very similar gene-expression profiles.[208,209]

Complex chromosomal abnormalities have been found in extranodal NK/T-cell lymphomas.[179,210-213] The most common changes are 6q21-q25 deletion (about 50%), 1q21-q44 gain (about 50%), and 17p11.2-p13.3 deletion (about 40%).[208,209,214-216] Specific chromosomal translocations have not been identified. In the commonly deleted region on 6q21, several candidate tumor suppressor genes (*PRDM1, ATG5, AIM1, PTPRK, HACE1,* and

FOXO3) with low-level transcripts have been identified.[214,217,218] Nonsense mutation and promoter hypermethylation have been reported in *PRMD1* (which plays an important role in NK-cell homeostasis),[218-220] and missense mutation in *FOXO3*.[217] Underexpression of *PTPRK* may lead to STAT3 activation, since PTPRK normally dephosphorylates phospho-STAT3.[221] The pathogenetic role of *HACE1* is controversial.[222-224]

Activation of the JAK-STAT signaling pathway through mutations (*JAK23, STAT3,* and *STAT5B* mutations in a low percentage of cases) and phosphorylation appears to play a key role in the pathogenesis of extranodal NK/T-cell lymphoma.[209,225-231] Recurrent mutations are found in RNA helicase *(DDX3X, DHX58)*, epigenetic regulators *(KMT2D, BCOR, ARID1A, EP300)*, and tumor suppressor genes *(TP53, MGA)*.[232-236] There is also activation of NF-κB pathway and overexpression of MYC and EZH2.[237,238] PDL1 expression is upregulated, postulated to be driven by LMP1 or STAT3.[239,240]

Three molecular subtypes of extranodal NK/T-cell lymphoma have been proposed.[236] The TSIM subtype (most common subtype: 55%) is characterized by JAK/STAT activation, *TP53* mutation, del6q21, overexpression of PLD1, type II EBV latency with expression of lytic gene *BALF3,* and NK-cell origin. The MB subtype is characterized by *MGA* mutation, 1p22.1/BRDT loss of heterozygosity, MYC overexpression, type I EBV latency, T-cell origin, and poor outcome. The HEA subtype is characterized by aberrant histone acetylation, mutations in *HDAC9, EP300,* and *ARID1A,* overexpression of DAXX and MEF2C, NF-κB activation, type II EBV latency with expression of lytic gene *BNFR1,* T-cell origin, and best outcome. Further studies are needed to validate the significance of this molecular subtyping.

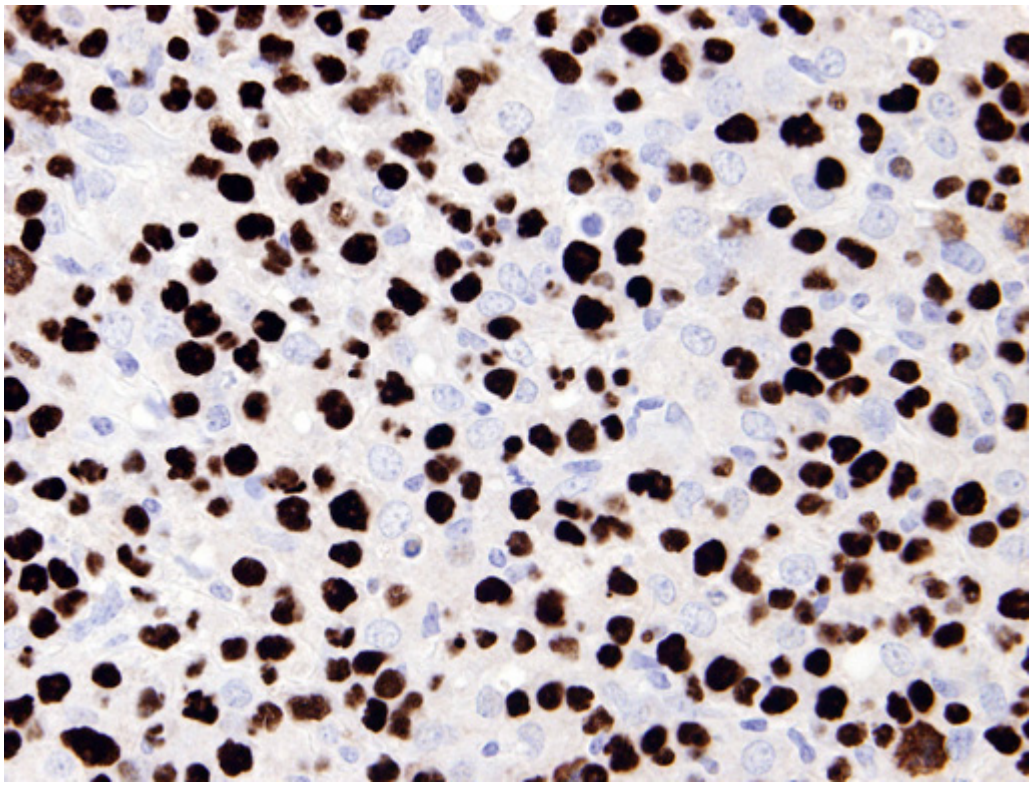

FIGURE 29-23 Nasal NK/T-cell lymphoma. In situ hybridization for EBER labels the nuclei of most lymphoma cells.

Postulated Cell of Origin

The likely normal counterpart is an activated mature NK cell in most cases, and an cytotoxic T lymphocyte in others.[186,209]

There are no criteria which can absolutely distinguish true NK-cell lineage from cytotoxic T-cell lineage among lymphomas. One approach is to use a combination of TCR expression and TR gene rearrangement to assign lineage.[144] Lack of expression of αβ and γδ TCR proteins, together with lack of clonal TR gene rearrangements, suggests NK lineage. Expression of TCR protein (irrespective of TR gene rearrangement status), or lack of TCR protein expression but

presence of clonal TR gene rearrangement, will suggest T-cell lineage. The caveats of the approach are limitations in sensitivity of TCR immunohistochemistry,[203] possible loss of TCR expression in some T-cell lymphomas,[203] and possible false negative results of TR gene rearrangement studies by polymerase chain reaction (PCR). Overall, about 85% of nasal NK/T-cell lymphomas are considered to be of NK lineage, while about 50% of extranasal NK/T-cell lymphomas are considered to be of NK lineage.[144,167,188] The distinction between NK and cytotoxic T cell lineage, however, is not of prognostic importance.[144]

Clinical Course

Although patients with nasal NK/T-cell lymphoma usually present with localized disease; dissemination to various sites frequently occurs either early or late during the clinical course.[139,241] Chemoradiotherapy with nonanthracycline-containing regimens is the single most important key to successful outcome, with 5-year overall survival rate of about 70% being achievable.[242-246]

For patients with advanced stage nasal or extranasal NK/T-cell lymphoma, chemotherapy with anthracycline-based regimens such as CHOP have produced disappointing results, with overall 5-year survival rate of only approximately 10%,[139,143,247,248] which may be attributable to frequent expression of multidrug resistance gene (P-glycoprotein).[249] Favorable overall response has been reported with regimens including L-asparaginase, with response around 80% being reported.[246,250-253]

Immune checkpoint inhibitors hold promise in treatment of patients with relapsed or refractory disease, being able to achieve

complete remission in a proportion of these patients.[254-256]

Rare cases of nasal or extranasal (particularly cutaneous) NK/T-cell lymphoma may pursue an indolent or self-regressing clinical course,[257] but it is currently not possible to predict which cases will behave in this fashion.

Differential Diagnosis

The main differential diagnoses are listed in **Table 29-3**. For lesions composed mostly of large lymphoid cells, it is easy to recognize their neoplastic nature, but the problem is distinction from diffuse large B-cell lymphoma and non-hematolymphoid malignancies. This problem can usually be readily solved by immunohistochemistry.

For lesions composed predominantly of small-sized or mixed cells, distinction from reactive or inflammatory conditions can be very difficult (**Table 29-3**). In extranodal sites, the normal small lymphocytes often appear mildly atypical, with slightly enlarged and irregularly folded nuclei, and thus morphologically overlap with the small neoplastic cells seen in extranodal NK/T-cell lymphoma (Figs. **29-24** and **29-25**). Presence of some or all of the following morphologic features would favor a diagnosis of lymphoma: (1) dense infiltrate causing separation or destruction of the mucosal glands, (2) prominent tissue necrosis and ulceration, (3) angioinvasion, (4) presence of mitotic figures in a small-cell-predominant lymphoid infiltrate, (5) clear cells, and (6) a significant population of atypical medium-sized cells with irregular nuclei (**Fig. 29-26**). The diagnosis can be confirmed by immunohistochemical demonstration of sheets of CD3ε-positive CD56-positive cells. If the infiltrate is CD3ε positive CD56 negative, positive immunostaining

for TIA-1 and in situ hybridization for EBER will support the diagnosis. See Pearls and Pitfalls for assessment of posttreatment biopsies (**Fig. 29-27**).

Acute EBV-positive cytotoxic T-cell lymphoid hyperplasia of the upper aerodigestive tract, a rare self-limiting condition, can mimic nasal NK/T-cell lymphoma.[258] The patients are young, with a median age of 16 years. They present with acute onset of mass lesion in the upper aerodigestive tract, commonly accompanied by cervical lymphadenopathy and fever. Biopsy shows infiltration of atypical small-to-medium-sized lymphoid cells that represent cytotoxic T cells (CD3 positive, CD5 positive, cytotoxic marker positive, CD56 negative) and express EBER. This condition differs from the usual acute EBV infections (infectious mononucleosis) in implicating T cells rather than B cells, thus showing significant morphologic and immunophenotypic overlap with extranodal NK/T-cell lymphoma. Features suggesting this diagnosis over the latter include young patient age, acute onset of symptoms, presence of cervical lymphadenopathy and fever, CD5 positive lymphoid cells, and CD56 negative.

Wegener's granulomatosis, a destructive lesion of the upper respiratory tract, shares many morphologic features with nasal NK/T-cell lymphoma in the form of mixed inflammatory infiltrate, ulceration, necrosis, and vasculitis or vasculitis-like lesions. The same features helpful for distinction between extranodal NK/T-cell lymphoma and reactive/inflammatory also apply.

Lymphomatoid granulomatosis represents a distinct form of T-cell-rich large B cell lymphoproliferative disorder showing a strong

association with EBV.[186-188,259] The atypical cells express B lineage markers rather than NK/T cell markers.

Primary cutaneous γδT-cell lymphoma shows morphologic and immunophenotypic overlap with extranodal NK/T-cell lymphoma (including frequent expression of cytotoxic markers and CD56), but can be distinguished by a usual lack of EBV.[203] Dilemma in classification, however, may arise when a cutaneous T-cell lymphoma is shown to be γδ TCR positive and EBV positive, raising the possibilities of extranodal NK/T-cell lymphoma and the rare occurrence of EBV in primary cutaneous γδT-cell lymphoma.[203,260,261]

Herpes simplex infection can simulate nasal NK/T-cell lymphoma because of the presence of a mass lesion, a dense lymphoid infiltrate with necrosis, and CD56 expression by the lymphoid cells.[262] The presence of scattered herpesvirus inclusions, lack of angioinvasion, expression of CD4 by the T-cell infiltrate, and absence of EBV support this diagnosis over extranodal NK/T-cell lymphoma.

Indolent NK-cell lymphoproliferative disorder of the gastrointestinal tract (formerly known as *NK-cell enteropathy* or *lymphomatoid gastropathy*) is a self-limiting NK-cell proliferation affecting single or multiple sites in the gastrointestinal tract.[6,7,263-265] The patients are asymptomatic or present with vague gastrointestinal symptoms. Endoscopy reveals a superficial small elevated lesion (~1 cm) or ulcer, often with hemorrhage and edema. The lesion shows spontaneous resolution, persistence, or recurrence. Biopsy shows mucosa expanded by atypical medium-sized lymphoid cells with indented or irregularly folded nuclei. Some lymphoid cells contain brightly eosinophilic granules. The atypical lymphoid cells

show an NK-cell immunophenotype (CD3 positive, CD5 negative, CD56 positive, cytotoxic markers positive). Features favoring the diagnosis of indolent NK-cell lymphoproliferative disorder over extranodal NK/T-cell lymphoma are as follows: (1) small, relatively circumscribed and superficial lesion; (2) lack of angioinvasion or necrosis; and (3) negative for EBER.

Aggressive Nk-Cell Leukemia

Synonyms and Related Terms

WHO revised 4th ed.: Aggressive NK-cell leukemia
WHO proposed 5th ed.: Aggressive NK-cell leukemia

Definition

Aggressive NK-cell leukemia is a systemic neoplasm of NK cells with primary involvement of peripheral blood and bone marrow and a fulminant clinical course, and frequent association with EBV (capsule summary in **Box 29-7**).[266,267] In contrast to the usual leukemias, neoplastic cells can be sparse in the peripheral blood and bone marrow.

Table 29-3

EBER, EBV-encoded RNA; *EBV,* Epstein-Barr virus; *ENKTL-NT,* extranodal NK/T-cell lymphoma, nasal type; *H&E,* hematoxylin and eosin; *NK,* natural killer; *TdT,* terminal deoxynucleotidyl transferase.

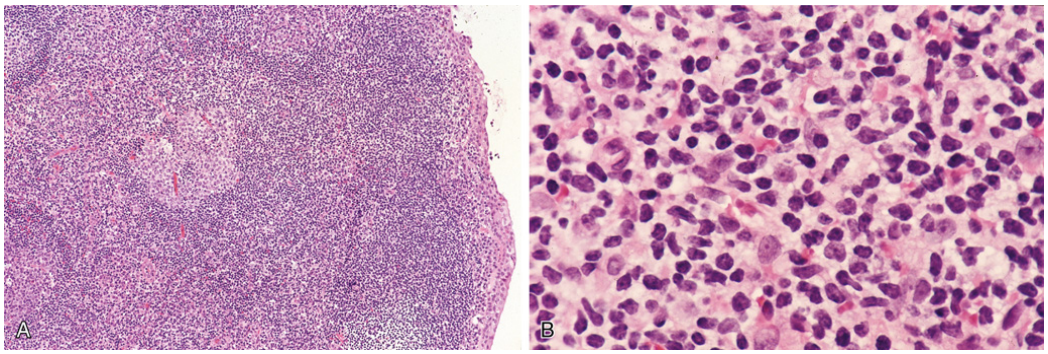

FIGURE 29-24 Nasopharyngeal mucosa with reactive lymphoid hyperplasia.A, The mucosa is rich in lymphoid cells, and reactive lymphoid follicles are present. **B,** Closer examination of the interfollicular zone shows that the small lymphoid cells are often slightly larger than small lymphocytes and can exhibit nuclear foldings. Thus there is cytologic overlap of mucosal reactive lymphoid cells and NK/T-cell lymphoma cells (compare with **Fig. 29-8**).

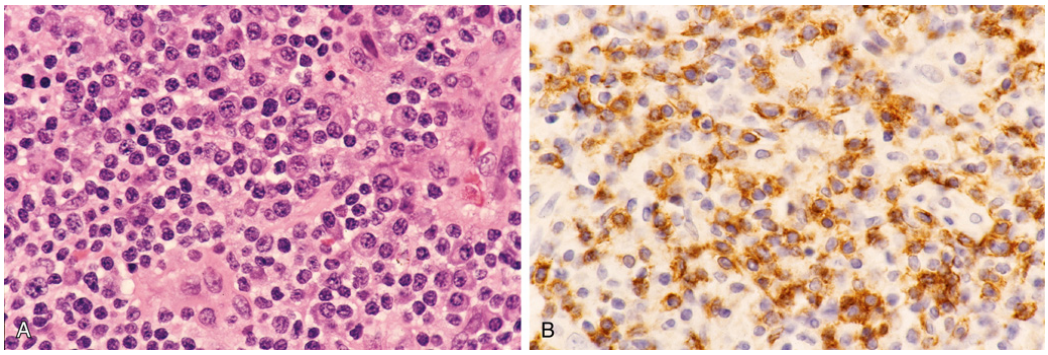

FIGURE 29-25 Nasal NK/T-cell lymphoma: difficult-to-diagnose case.A, The predominance of small lymphoid cells with round nuclei and admixed plasma cells suggests a benign lymphoid infiltrate. Nonetheless, there are features suggestive of lymphoma such as ulceration and loss of mucosal glands (not shown). **B,** Immunostaining shows many CD56-positive cells (which are also CD3ε positive), supporting a diagnosis of nasal NK/T-cell lymphoma. In the normal or reactive mucosa, CD56-positive cells are not present in such large numbers.

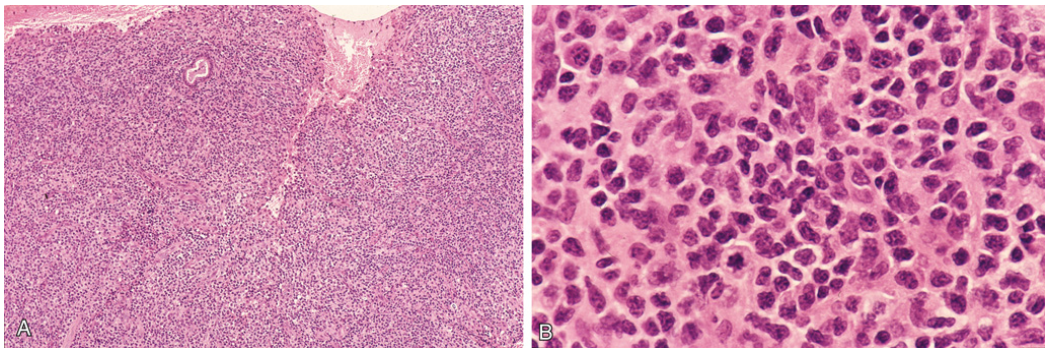

FIGURE 29-26 Nasal NK/T-cell lymphoma: histologic features supporting a diagnosis of lymphoma over reactive lymphoid hyperplasia.A, An extensive and dense lymphoid infiltrate with loss of mucosal glands. **B,** Definite cytologic atypia in the lymphoid cells, if present, supports a diagnosis of lymphoma. Compared with **Fig. 29-24**, the cells are slightly larger and show more irregular nuclear foldings. Readily found mitotic figures in a small lymphoid infiltrate are another feature suggestive of lymphoma.

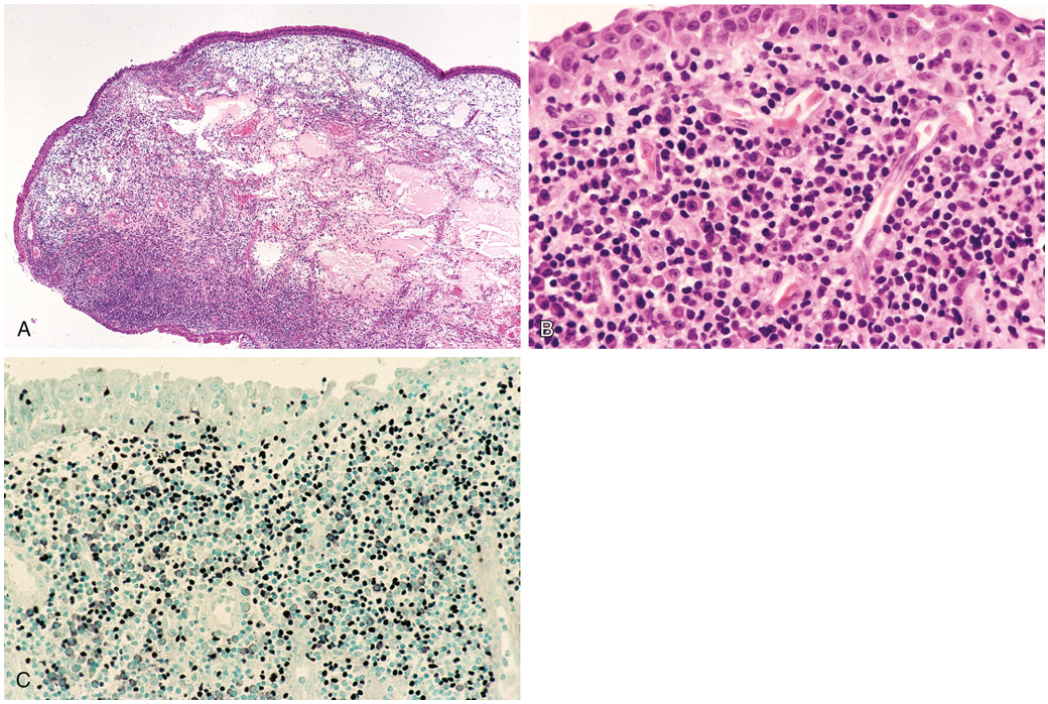

FIGURE 29-27 Nasal NK/T-cell lymphoma: posttreatment biopsy.A, The nasal mucosa appears hypocellular in most areas. **B,** In the more cellular areas, plasma cells are admixed with small lymphoid cells, suggesting a benign lymphoid infiltrate. **C,** Surprisingly, numerous Epstein-Barr virus–encoded RNA (EBER)–positive cells are present, indicating that there is still residual disease.

Box 29-7 Major Diagnostic Features of Aggressive NK-Cell Leukemia

Clinical Features and Behavior

- More prevalent in Asians
- Age: Teenage to middle age (median 40 years)
- Sex: M = F
- Presentation: Ill patient with fever, constitutional symptoms, hepatosplenomegaly, generalized lymphadenopathy, and sometimes bleeding tendency
- Fulminant clinical course with cytopenia, coagulopathy, and multiorgan failure, often resulting in death within a few weeks

Morphology

- Peripheral blood or marrow smear: Few to numerous large granular lymphocytes, many of which are atypical (such as irregular nuclear foldings or very large size) or immature (such as open chromatin or distinct nucleoli).
- Involved tissues: Usually dense, permeative, and monotonous infiltrate of medium-sized lymphoid cells with prominent apoptosis. Angiocentric growth and necrosis common.

Immunophenotype and Genotype

- CD3ε^{+}, surface CD3^{-}, CD5^{-}, CD56^{+}, CD16$^{+/-}$, cytotoxic molecule+
- EBV positive in majority of cases
- TR genes germline

Epidemiology and Etiology

The disease occurs with a much higher frequency in Asians compared with Whites, and thus ethnic factors may play a role in disease susceptibility. It is strongly associated with EBV, which is present in approximately 90% of cases.[268-273] Rare cases may evolve from CAEBVD of T or NK type,[72,73,103] nasal NK/T-cell lymphoma,[274] or chronic lymphoproliferative disorder of NK cell (NK large granular lymphocytic leukemia)[275]; aggressive NK-cell leukemia arising in the latter setting is EBV negative.

The patients are typically adolescents or young adults, but older patients can also be affected. The median age is 40 years.[186,266,268,271,272,276-279] There is no sex predilection.

Clinical Features

The typical presentations are fever, hepatosplenomegaly, and a leukemic blood picture.[186,266,268,271,272,276,277] Lymphadenopathy may be present. Skin nodules are uncommon, but some patients may have nonspecific skin rash. The patients are often very ill and are commonly complicated by hemophagocytic syndrome.[276,278] Serum lactate dehydrogenase level is often markedly elevated, as is circulating Fas ligand.[280,281] It has been postulated that the systemic shedding of large quantities of Fas ligand from the tumor cells may contribute to the multiorgan failure commonly seen in aggressive NK-cell leukemia—binding of Fas ligand to Fas, which is normally expressed in many different types of normal cells, results in apoptosis of the Fas-bearing cells.

Morphology

Circulating leukemic cells account for <5% to >80% of lymphocytes. They often exhibit a range of appearances in an individual case, from normal-looking to immature or pleomorphic large granular lymphocytes (**Fig. 29-28**). They have round nuclei with condensed chromatin, or larger nuclei with irregular foldings. Nucleoli can be prominent in some cases. The cytoplasm is moderate to abundant in amount, and is lightly basophilic, with variable numbers of fine and occasionally coarse azurophilic granules. In the bone marrow, the neoplastic cells constitute 6% to 92% of all nucleated cells,[277] with the pattern of involvement ranging from diffuse interstitial to subtle and patchy (**Fig. 29-29**).[277]

In histologic sections, there is a diffuse, destructive, and permeative infiltrate consisting of cells with round or irregular nuclei, fairly condensed chromatin, and a thin-to-moderate rim of pale or amphophilic cytoplasm. Interspersed apoptotic bodies and zonal cell death are common (**Fig. 29-30**). Angioinvasive-angiodestructive growth is also frequently noted.[272]

Immunophenotype and Molecular Findings

The typical immunophenotype is $CD2^+$, surface $CD3^-$, cytoplasm $CD3\varepsilon^+$, TCR^-, $CD5^-$, $CD56^+$, $CD16^+$, and cytotoxic markers+ (**Fig. 29-31**). CD57 is often negative (**Table 29-2**).[143,186,216,268,271,272]

The TR genes are typically not rearranged. EBV is reported in about 90% of cases.[268-271,276,277,282] The EBV-negative subset shows clinicopathologic features similar to the EBV-positive cases.[208,283-286]

Although previous comparative genomic hybridization studies suggest similar genetic changes in aggressive NK-cell leukemia and

extranodal NK/T-cell lymphoma, such as 3p positive, 6q negative, 11q negative, 12q positive,[179,210] an array-based comparative genomic hybridization study reveals significant differences between the two.[213] For instance, 7p negative, 17p negative, and 1q positive are frequent in aggressive NK-cell leukemia but not in extranodal NK/T-cell lymphoma, while the 6q negative is much more common in the latter.

Molecular studies indicate prominent STAT3 activation and MYC expression.[287] Mutations are commonly found in genes of the JAK-STAT and RAS-MAPK pathways, histone modifying genes (*TET2, CREBBP,* and *KMT2D*), *DDX3X,* and *TP53*.[279,287-289]

Clinical Course

Aggressive NK-cell leukemia pursues an acute fulminant course, frequently complicated by bleeding, coagulopathy, hemophagocytic syndrome, and multiorgan failure. The median survival is 2 months.[277,279] Response to conventional chemotherapy is usually poor,[282] but L-asparaginase-based chemotherapy may produce favorable response in some cases.[279,286,290] alloHSCT is currently the only available treatment that may effect a cure, albeit in only a small fraction of patients, particularly those in complete remission at the time of transplantation.[279,291,292]

Differential Diagnosis

Aggressive NK-cell leukemia must be distinguished from the more common T-cell large granular lymphocytic leukemia, which is EBV negative and frequently pursues an indolent clinical course.[293] Patients with T-cell large granular lymphocytic leukemia are

generally older (mean 55–65 years), and commonly present with infection, pure red cell aplasia, or neutropenia, and may be associated with rheumatoid arthritis. The circulating lymphoid cells do not exhibit atypia or immature appearance as commonly observed in aggressive NK-cell leukemia. The leukemia cells show a surface CD3-positive, CD4-negative, CD8-positive phenotype and clonally rearranged TR genes; CD56 is usually negative.

Chronic lymphoproliferative disorder of NK cells (NK-large granular lymphocytic leukemia) is clinically and morphologically similar to T-cell large granular lymphocytic leukemia, but differs in showing surface CD3 negative, CD56 positive or negative, and germline TR genes.[6,7,270,293-297] It differs from aggressive NK-cell leukemia in the following features: (1) indolent clinical course, (2) lack of hepatosplenomegaly, (3) lack of atypia in the large granular lymphocytes, (4) frequent expression of CD16 and CD57, and (5) lack of association with EBV.[270,298-301]

Aggressive NK-cell leukemia shows many similarities with ENKTL-NT, but the clinical features are different. It affects younger patients with acute fulminant presentation, and lacks nasal involvement. Admittedly, in some circumstances, their distinction can be very difficult, and may be a matter of semantics.

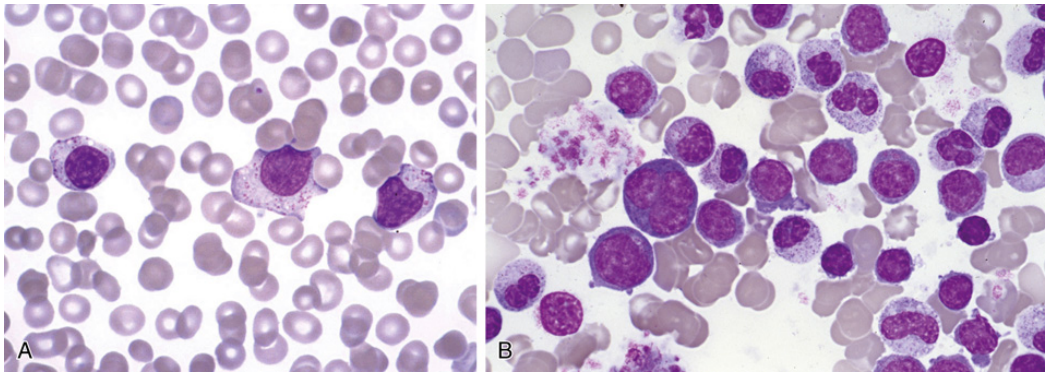

FIGURE 29-28 Aggressive NK-cell leukemia: peripheral blood or buffy coat findings.A, In the peripheral smear, there are large granular lymphocytes with atypia. Nucleolus is seen in the cell in the *center field*. **B,** Buffy coat smear shows many lymphoid cells with immature nuclear chromatin, distinct nucleoli, and cytoplasmic granules. There are admixed immature cells of the granulocytic series.

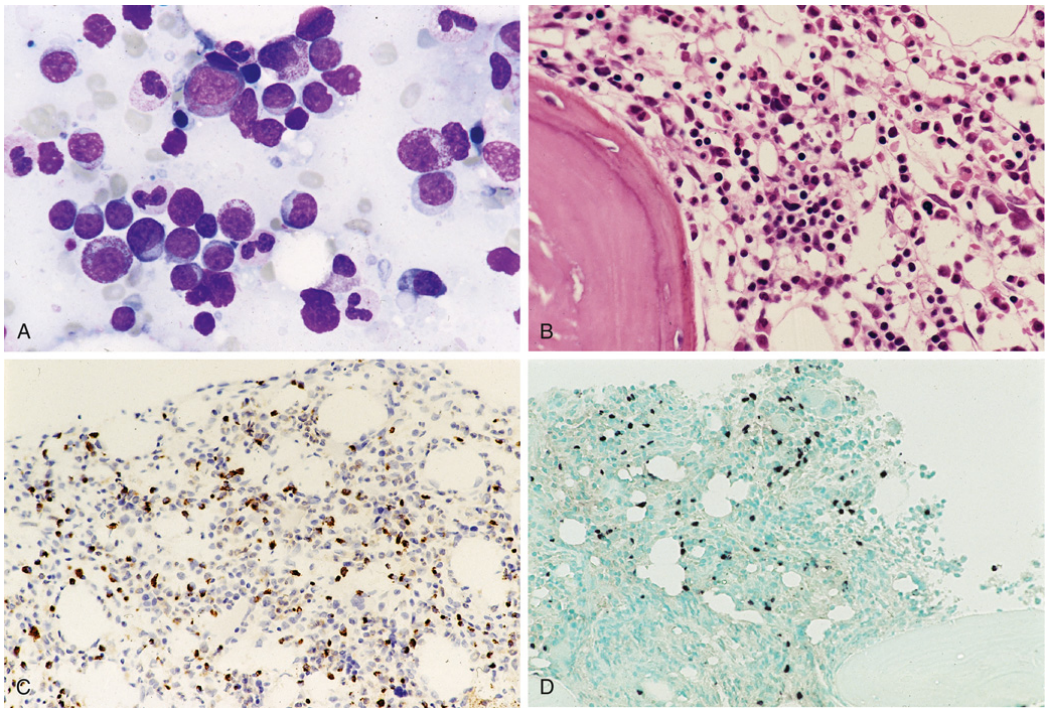

FIGURE 29-29 Aggressive NK-cell leukemia: bone marrow findings.**A,** In the marrow smear, the leukemic cells have round nuclei, lightly basophilic cytoplasm, and fine azurophilic granules. They occur singly or in small groups among the myeloid cells. **B,** In bone marrow biopsy, the subtle interstitial infiltrate of leukemic cells is often difficult to recognize. **C,** The scattered leukemic cells are much easier to appreciate by immunostaining for cytotoxic molecule such as TIA-1. **D,** These cells can similarly highlighted on in situ hybridization for EBER.

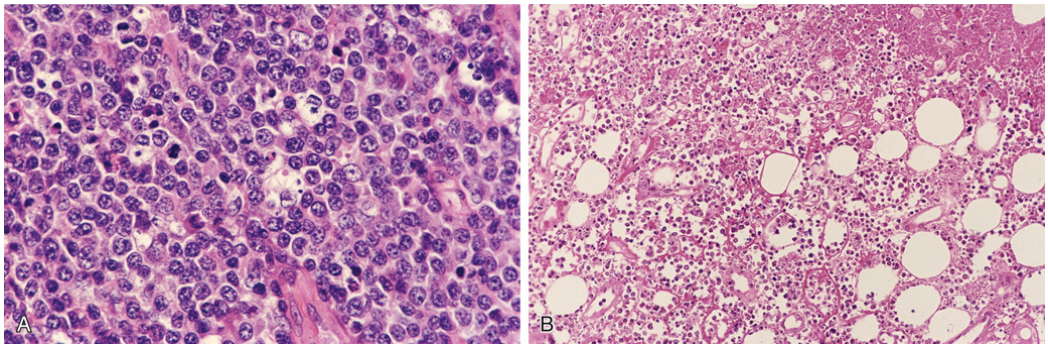

FIGURE 29-30 Aggressive NK-cell leukemia: tissue manifestations. **A,** Lymph node shows a monotonous infiltrate of medium-sized cells with round nuclei. There are many admixed apoptotic bodies. Because of histologic resemblance to plasmacytoid dendritic cells, the differential diagnosis of Kikuchi-Fujimoto lymphadenitis may be raised. **B,** The pericardial tissue is infiltrated by neoplastic cells, with necrosis and many apoptotic bodies.

Aggressive NK-cell leukemia shows many similarities with systemic T-cell lymphoproliferative disorder of childhood clinically and pathologically, except that it rarely occurs in children, it is not always accompanied by fulminant hemophagocytic syndrome, CD56 is usually positive, and TR genes are not rearranged.

Primary Nodal Epstein-Barr Virus–Positive T/Nk-Cell Lymphoma

Synonyms and Related Terms

WHO revised 4th ed.: Subgroup within peripheral T-cell lymphomas

WHO proposed 5th ed.: EBV-positive nodal T- and NK-cell lymphoma

Definition

Primary nodal EBV-positive T/NK-cell lymphoma is, by definition, a nodal EBV-positive cytotoxic T-cell or NK-cell lymphoma. It presents more commonly in elderly or immunodeficient patients, lacks nasal involvement, and is more often of T-cell rather than NK-cell lineage. This was not a separate entity in the revised WHO 4th ed. and included as an EBV-positive variant of peripheral T-cell lymphoma, NOS, but recognized as a distinct entity in the WHO 5th ed.[7] and as a provisional entity in the ICC.[6] It is a primarily nodal disease with predominantly nodal involvement, although the tumor may involve a limited number of extranodal organs except the nasal cavity. ENKTL-NT, aggressive NK-cell leukemia, and transformed lymphoma from EBV-negative mature T-cell lymphoma should be excluded (capsule summary in **Box 29-8**).

Epidemiology

Primary nodal EBV-positive T/NK-cell lymphoma is very rare. The regional distribution is similar to that of other types of EBV-associated T/NK-cell lymphoma/leukemia. So far, fewer than 100 cases have been reported, mainly from Japan,[302,303] Hong Kong,[304] and Korea.[305,306]

Pathophysiology

EBV can infect virtually all neoplastic cells and appears to play an important role in the pathogenesis of primary EBV-positive nodal T/NK-cell lymphoma. Although they have no definite evidence of immune deficiency, patients are often older adults with a history of other associated viral infections such as hepatitis B and hepatitis C or diabetes mellitus,[305] suggesting that these patients have impaired immune function that allows viral persistence. Gene-expression analysis revealed upregulation of immune response genes and activation of IFNγ, IL6/JAKL/STAT3, and NFκB with upregulation of PDL1 that allows immune evasion of EBV-infected cells.[305,307] Sustained EBV infection in T cells or NK cells and altered immune responses in immunocompromised older adult patients can lead to oncogenic transformation of EBV-infected cells with the aid of driver mutation.

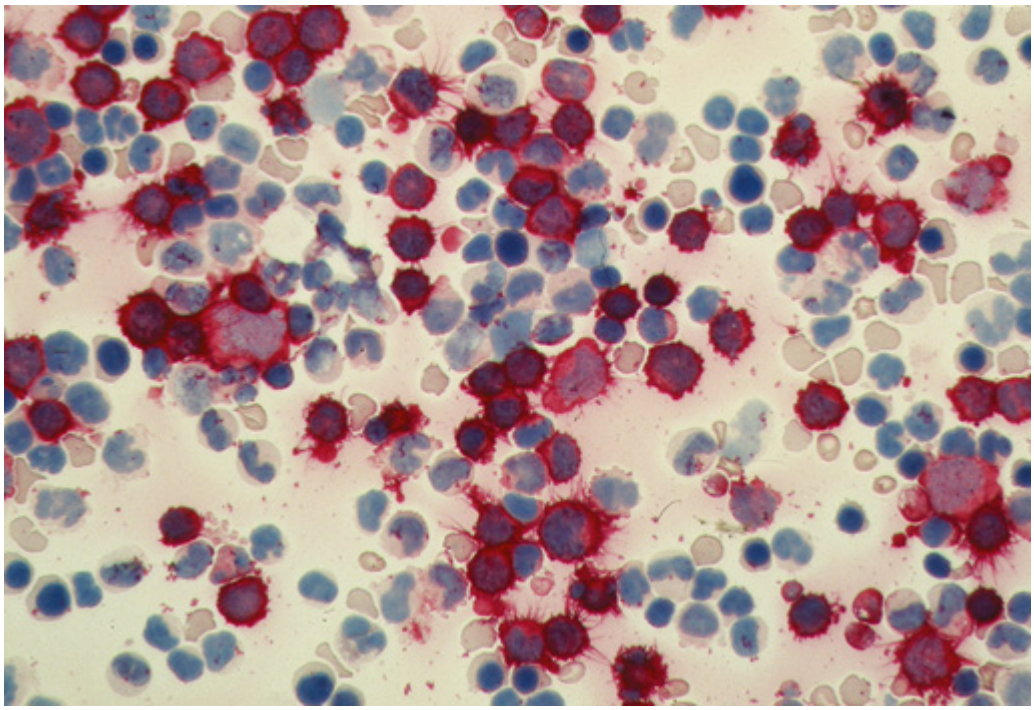

FIGURE 29-31 Immunocytochemistry of aggressive NK-cell leukemia.In the marrow smear, the atypical cells show cell membrane staining for the NK-cell marker CD56.

Clinical Features

The median age of patients is 62 years, but 31% of patients are younger than 50 years. The male-to-female ratio is 2:1. Patients present in stage III or IV in 88% of cases. Patients may have anemia (64%), thrombocytopenia (50%), elevated LDH (77%), or hemophagocytosis (22%). B symptoms are seen in 77% of patients.[305-309] Patients present primarily with nodal disease, and there are no nasal lesions. There may be limited extranodal involvement including the liver in 35%, spleen in 46%, and bone marrow in 27% of patients.[308,309]

Morphology

Lymph nodes show diffuse infiltration of pleomorphic small-to-medium-sized and often medium-to-large-sized cells. The cytomorphology of these cells is variable—more commonly centroblastic, often anaplastic, or plasmacytoid (**Fig. 29-32**).[306-309] Tumor cells have a round or irregular nucleus with hyperchromasia and often prominent nucleoli. Polymorphic lymphoid cells with Reed-Sternberg (RS) cell–like large binucleated or multinucleated giant cells are often found.[305] Some cases show extensive necrosis, many apoptotic bodies, and angiocentric growth patterns as seen in extranodal NK/T-cell lymphomas. An associated inflammatory infiltrate comprising small lymphocytes, plasma cells, and granulomas is often found.[305]

Box 29-8 Major Diagnostic Features of Primary Nodal EBV-Positive T/NK-Cell Lymphoma

EBER, EBV-encoded RNA; *EBV,* Epstein-Barr virus; *NK,* natural killer; *RS,* Reed-Sternberg.

Definition

- Primary nodal EBV-positive cytotoxic T- or NK-cell lymphoma

Diagnostic Criteria

- Cytotoxic T-cell or NK-cell lymphoma presenting in the lymph node
- EBV positive in virtually all neoplastic cells

- No nasal lesion
- May involve a limited number of extranodal organs

Clinical Features and Behavior

- Most patients are older adults (median age, 62 years)
- Present with high clinical stage (stage III/IV in 88% of cases)
- Aggressive clinical course (median survival, 4 months)
- Cause of death: Septic shock or disease progression

Morphology

- Variable cytomorphology
- More commonly centroblastic, often anaplastic, or plasmacytoid
- RS cell–like large binucleated or multinucleated giant cells can be observed

Immunophenotype and Genotype

- Mainly composed of cytotoxic T cells or rarely NK cells
- Usually CD3 positive, CD8 positive, betaF-1 positive, cytotoxic granule positive
- A minority of cases show γδT-cell phenotype
- EBER-positive in vast majority of neoplastic cells
- T-cell receptor gene rearrangement: Usually monoclonal

Immunophenotype and Genetics

Based on the TR gene rearrangement and expression of the TCR protein, most cases of primary EBV-positive nodal T/NK-cell lymphoma comprise cytotoxic T cells.[305,308] NK-cell forms are uncommon.[303,304,307] The typical immunophenotype of primary EBV-positive nodal T/NK-cell lymphoma is CD3-positive, CD8-positive, TIA-1-positive, and granzyme B–positive, although CD4 is expressed in a minority cases. Unlike extranodal NK/T-cell lymphoma, expression of CD56 is infrequent. TCR staining reveals expression of TCR βF1 in 58%, TCR-γ in 13%, and TCR-silent in 29% of patients.[309] The TCR-silent type is characterized by high CD30 positivity. As in extranodal T/NK-cell lymphoma, virtually all tumor cells are positive for EBER in situ hybridization.[305-309]

Analysis of viral latency genes revealed a type 3 EBV latency in one-third of cases and type 2 latency in the remainder.[307] Compared with cytotoxic PTCL, NOS, primary nodal EBV-positive T/NK cell lymphoma is a genomically stable disease. Genetic analysis revealed frequent mutation involving *TET2, PIK3CD, STAT3, DDX3X,* and *PTPRD*.[307]

Prognosis

Primary nodal EBV-positive T/NK-cell lymphoma exhibits an aggressive clinical course, with a median survival of 4 months.[305,308,309] The prognosis is similar to that of extranasal lymphoma of ENKTL-NT[308,309] and poorer than cytotoxic PTCL, NOS.[307] The cause of death includes septic shock or disease progression.[305]

Differential Diagnosis

ENKTL-NT can show nodal involvement of a tumor at the time of the initial presentation in 30% of nasal lymphoma cases and 70% of extranasal lymphoma cases.[310] Primary nodal EBV-positive T/NK-cell lymphoma tends to show centroblastic cytology and RS cell–like binucleated or multinucleated giant cells, which are uncommon findings in ENKTL-NT.[308,309] The CD4-negative, CD8-negative, CD56-positive immunophenotype is found most frequently in ENKTL-NT, whereas primary nodal EBV-positive T/NK-cell lymphoma usually expresses CD8 but not CD4 and CD56.[305,308,309] Despite these differences, the two diseases show significant overlap in their histology and immunophenotype. Clinical correlation and examination of the nasal cavity are necessary to exclude ENKTL-NT.

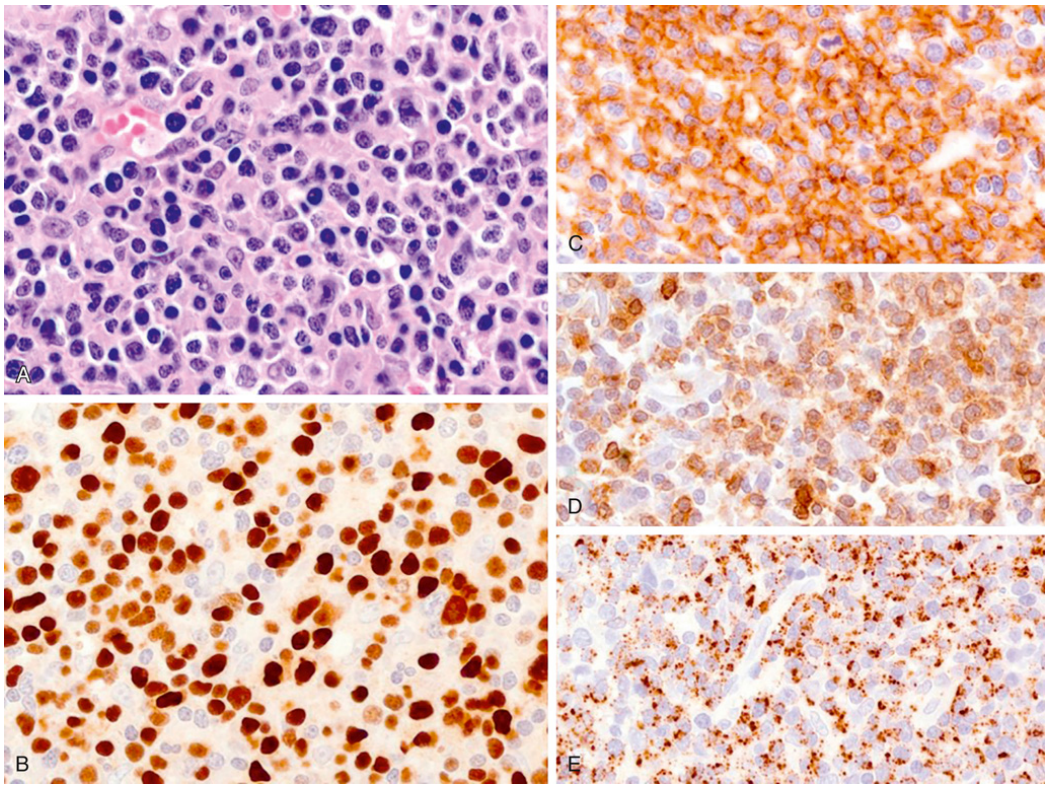

FIGURE 29-32 Primary Epstein-Barr virus–positive nodal T/NK-cell lymphoma.A, The lymph node is infiltrated by relatively monotonous medium-to-large-sized pleomorphic neoplastic cells. **B,** The vast majority of neoplastic cells are positive for Epstein-Barr virus–encoded RNA (EBER) in situ hybridization. Neoplastic cells are positive for CD8 **(C),** betaF-1 **(D)**, and TIA-1 **(E).**

Aggressive NK-cell leukemia and primary nodal EBV-positive T/NK-cell lymphoma of NK-cell lineage may show pathologic and clinical similarities. Aggressive NK-cell leukemia is characterized by systemic proliferation of malignant NK cells with involvement of the bone marrow, spleen, and liver. Nodal involvement at the time of

presentation is reported in 20% to 26% of cases,[283,286] although lymphomatous features involving predominantly lymph nodes are uncommon.[304] Rare cases of nodal EBV-positive NK-cell lymphoma have been reported under the term *aggressive NK-cell lymphoma* or *lymphomatous features of aggressive NK-cell leukemia*.[272] Previously, these cases were believed to be a nonleukemic counterpart of aggressive NK-cell leukemia, but they seemed to correspond to primary nodal EBV-positive T/NK-cell lymphoma of NK-lineage.

EBV infection in T-cell lymphoma is also found in other mature T-cell lymphomas including angioimmunoblastic T-cell lymphoma and peripheral T-cell lymphoma, unspecified (PTCL-NOS). Unlike primary nodal EBV-positive T/NK-cell lymphoma, in which EBV infects neoplastic T cells, the EBV genome is found mainly in non-neoplastic B cells, although it may also be identified in T cells or null cells.[311] EBV-positive PTCL can originate from the secondary transformation of low-grade EBV-negative T-cell lymphomas.[312] Secondary EBV infection of an established malignant T-cell clone can occur in vivo and may contribute to its aggressive transformation.[313] Primary nodal EBV-positive T/NK-cell lymphoma is diagnosed after exclusion of such transformed lymphomas.

Pearls and Pitfalls

EBV-Positive Lymphoproliferative Diseases of Childhood

- Correct diagnosis of Epstein-Barr virus (EBV)–positive lymphoproliferative diseases of childhood requires the

integration of clinical, immunophenotypic, genotypic, and morphologic features.

- EBV-associated hemophagocytic lymphohistiocytosis (EBV-HLH) is a hyperinflammatory syndrome caused by dysregulated immune response and hypercytokinemia secondary to EBV infection. EBV-HLH and systemic EBV-positive T-cell lymphoma of childhood share a significant overlap in clinical presentation and pathologic changes. The distinction between these two diseases is often challenging.
- Chronic active EBV disease (CAEBVD) includes a constellation of clinical syndromes that vary in their aggressiveness. Elevated EBV load in blood and tissue with clinical symptoms lasting more than 3 months is mandatory for making a diagnosis. Histologic changes in CAEBVD are nonspecific and appear to be inflammation or reactive lymphoid hyperplasia. Double procedure for EBV–encoded RNA (EBER) in situ hybridization with immunohistochemistry for CD3 or CD56 is important to recognize EBV-infected T or NK cells in tissue biopsy.
- Hydroa vacciniforme lymphoproliferative disorder (HVLPD) and severe mosquito bite allergy are cutaneous EBV-associated proliferations of T cells and NK cells in which cytokines and chemokines contribute to the homing of EBV-infected cells to sites of inflammation, leading to the characteristic symptoms.
- HVLPD is divided into classic and systemic forms based on the clinical features.

    - Classic HVLPD is an indolent and self-limited disease involving only the skin.
    - Systemic HVLPD shows systemic symptoms during the acute phase of the disease and might progress to lymphoma. In severe cases, similar treatment as CAEBVD is required.
- Systemic EBV-positive T-cell lymphoproliferative disorder of childhood may appear deceptively benign cytologically, but it pursues an aggressive clinical course.

Extranodal NK/T-Cell Lymphoma, Nasal Type

- The discrepancy between surface CD3 staining (negative) and cytoplasmic CD3ε staining (positive) in extranodal NK/T-cell lymphoma, nasal type (ENKTL-NT) is explainable by the presence of only subunits of CD3 in the cytoplasm but not the completely assembled CD3 molecule that is recognized by the surface CD3 antibodies such as Leu4 and T3.

Specificity of CD56 for NK/T-Cell Lymphoma

- CD56 expression is not specific for NK/T-cell lymphoma, but it is also expressed in some peripheral T-cell lymphomas (particularly those expressing γδ TCR), acute myeloid leukemia, myeloma, small-cell neuroendocrine carcinoma, rhabdomyosarcoma, and some other tumors.
- Thus a diagnosis of ENKTL-NT should not be based on CD56 expression alone, but should be supplemented by positive

immunostaining with other leukocyte markers (such as CD3ε and CD2).

Method of Choice for Detection of EBV in Extranodal NK/T-Cell Lymphoma, Nasal Type

- The preferred and most sensitive method for demonstration of EBV in ENKTL-NT is in situ hybridization for EBER.
- Immunostaining for EBV LMP-1 may be weak or negative, and thus cannot be relied on for demonstration of EBV in this lymphoma type.
- Southern blot technique is of limited sensitivity, and furthermore requires fresh or frozen tissue.
- Polymerase chain reaction (PCR) for EBV is highly sensitive but is of limited value because even presence of rare bystander EBV-positive lymphocytes can give rise to a positive result.

Assessment of Posttreatment Biopsies for Nasal NK/T-Cell Lymphoma

- Since the nasal cavity is readily accessible for biopsy, it is fairly common practice to take posttreatment biopsies in patients with nasal NK/T-cell lymphoma to determine whether there is residual lymphoma.
- Residual tumor is easy to recognize for lymphomas comprising predominantly large cells or if dense sheets of atypical lymphoid cells are evident.
- In most cases, the mucosa becomes hypocellular. Scattered residual lymphoma cells hiding among small lymphocytes or

residual lymphoma comprising small cells are very difficult, if not impossible, to recognize by morphologic assessment alone. Therefore it is prudent to perform immunostaining for CD56 and in situ hybridization for EBER to look for residual tumor cells. Positive cells must be present at least in aggregates or correlated with atypical cytology to be considered indicative of residual lymphoma. The presence of only isolated or groups of three to four positive cells is considered inconclusive, because low numbers of positive cells can be observed in the normal nasal or nasopharyngeal mucosa.

- With relapse, the cytologic features of the original lymphoma are usually maintained, but may sometimes change, such as from small-sized or medium-sized cells to large-sized cells, or vice versa. Occasionally CD56 expression is diminished or even lost in treated or relapsed lymphoma.

Clinical Management and Prognosis

DIFFERENTIAL DIAGNOSIS

History and Classification

The first detailed studies of what is now recognized as T-cell large granular lymphocytic leukemia (T-LGLL) were published in the 1970s and early 1980s.[1-3] These manuscripts described a disorder characterized by neutropenia or anemia that was associated with a proportionate and absolute increase in circulating granular lymphocytes that normally constituted only 10% to 20% of the peripheral blood lymphocytes. These studies also documented that the cytoplasmic granules of these lymphocytes were identical in ultrastructure to those of their normal counterpart (parallel microtubular arrays); formed sheep erythrocyte rosettes consistent with T-cell origin (now recognized as CD2 positivity); and expressed Fc receptors. Based on these attributes, the moniker *large granular lymphocytic leukemia* was coined. It should be noted, however, that this disorder was ascribed a number of different names in the early literature, including *CD8-positive T-cell chronic lymphocytic leukemia* and *T-gamma lymphoproliferative disorder*.

Our understanding of leukemias of large granular lymphocytes (LGLs) greatly advanced in the late 1980s and 1990s with the recognition of cytotoxic T cells and natural killer (NK) cells as discrete lymphocyte subsets and the advent of multicolor flow-cytometric immunophenotyping, which allowed these cell types to be distinguished and characterized in clinical specimens.[4] During this period, T-LGLL became the widely accepted nomenclature, with the fundamental defining attributes being an increase in granular lymphocytes with a CD8-positive T-cell phenotype, aberrant expression of the NK-cell lineage–associated antigens CD16 and CD57, and T-cell clonality as documented by the presence of clonal

T-cell receptor (TCR) gene rearrangements. Cases fulfilling these criteria often were associated with neutropenia and typically had an indolent clinical course. Also recognized during this time period were cases in which the increased granular lymphocytes had a CD3-negative, CD16-positive, CD56-positive NK-cell immunophenotype. Rendering a diagnosis of large granular lymphocytic leukemia in such cases was more problematic, however, as there were few methods to establish NK-cell immunophenotypic aberrancy and NK-cell clonality could not be readily assessed; these cells, by definition, lack TCR gene rearrangement. For these reasons, during this period, the diagnosis of *large granular lymphocytic leukemia of NK-cell lineage (NK-LGLL)* required a greater degree of clinical morbidity to confidently distinguish such cases from a potential reactive NK-cell lymphocytosis. Therefore, NK-LGLL was considered more aggressive than its T-cell counterpart in these earlier reports.[5]

More recently, further advances have improved our ability to identify chronic lymphoproliferative disorders of cytotoxic T cells and NK cells and provided potential insights into pathogenesis, including the identification of novel families of receptors for MHC-I and related proteins that are expressed by NK cells and a subset of cytotoxic T cells (collectively referred to as *natural cytotoxicity receptors, NCRs*).[6] Through the application of these tools, T-LGLL is now recognized as a disorder of memory cytotoxic T cells variably associated with cytopenias that typically has an indolent clinical course.[7] An NK-cell–derived counterpart to T-LGLL with similar clinical and laboratory features, including surrogate markers of clonality, has also been elucidated with the application of these new diagnostic tools. This is now referred to as *chronic*

lymphoproliferative disorder of NK cells (CLPD-NK) to distinguish it from the earlier NK-LGLL descriptions, which likely included more aggressive NK-cell malignancies that are described elsewhere in this text. However, it is noteworthy that, in the 5th edition of the World Health Organization (WHO) classification, the NK-LGLL nomenclature was reconsidered, as this terminology does reflect the close clinical relatedness between the T-cell and NK-cell forms of these disorders.

Definitions

T-LGLL is defined as a clonal or oligoclonal increase in peripheral blood cytotoxic T cells with granular lymphocyte morphology. Cytopenias are usually associated, yet they are not universally present and are not a defining attribute per se. Although increased circulating granular lymphocytes is the quintessential feature of T-LGLL, the use of an absolute LGL count as a diagnostic criterion has changed over time. In early disease definitions, an absolute LGL count of 2×10^9/L was used.[4] However, subsequently, bona fide T-LGLL not reaching this threshold were identified and, over time, it has come to be recognized that up to one-third of cases may have a count lower than 1×10^9/L.[8] For this reason, an absolute LGL count is no longer included as a disease-defining feature, although granular lymphocytes have an absolute count of greater than 0.5×10^9/L or account for more than 50% of the circulating lymphoid cells in most cases.

The T cells of T-LGLL are typically CD8-positive, αβ type, although cases that are either CD4 positive or of γδ lineage may uncommonly be encountered.[9,10] In virtually all cases, phenotypic abnormalities

are present, with co-expression of NK-associated antigens CD16 and/or CD57 considered pathognomic but not disease-specific.[11] In the vast majority of T-LGLLs, T-cell clonality can be detected through molecular analysis of TCR gene rearrangements, V-β flow cytometry, or TCR β constant 1 (TRBC1) flow cytometry.[12,13] Despite the presence of demonstrable T-cell clonality in T-LGLL on detailed molecular analysis, many cases appear oligoclonal. Therefore, clonality may not be demonstrated in all cases. In such instances, it is prudent to document persistence of the process by repeat studies after a period of 6 months to 1 year before rendering an unequivocal diagnosis.

CLPD-NK (or NK-LGLL) is also defined by an increase in peripheral blood granular lymphocytes (also associated with cytopenias in some instances); however, in this disorder, the lymphocytes are of NK-cell lineage, as documented by flow cytometry.[14] As in T-LGLL, in CLPD-NK, LGLs compose the majority of the peripheral blood lymphocytes, and, although the elevation in the absolute count is usually mild, it tends to be slightly higher than that seen in T-LGLL.[15] NK-cell immunophenotypic aberrancy is variably attributed as a feature of CLPD-NK. This variability likely reflects the limited NK-cell phenotyping, which is routinely used in many clinical laboratories, as aberrancy can be demonstrated in all cases when extensive NK-cell immunophenotyping (including antibodies to NCRs) is performed.[11,16] Because NK cells lack TCR gene rearrangements, evaluation of these genes is not part of the routine diagnostic evaluation or disease definition. The lack of a readily assessed marker of clonality in CLPD-NK places a greater emphasis on

documenting the persistence of the process for 6 months to 1 year. As in T-LGLL, cytopenias are frequently associated but not part of the disease definition.

Bone marrow immunohistochemistry revealing intrasinusoidal cytotoxic marrow infiltrates is detected in 75% or more of T-LGLL and CLPD-NK cases.[17,18] Likewise, studies have demonstrated that *STAT3* mutation is present in approximately 40% of both T-LGLLs and CLPD-NKs.[19] Therefore, these features are coming to be accepted as defining characteristics of these conditions, although neither is specific to T-LGLL or CLPD-NK.

Etiology and Epidemiology

Antigenic stimulation is considered a primary etiologic event in both T-LGLL and CLPD-NK, although no singular causative agent or predisposing factors have been identified for either condition. Serologic studies have demonstrated that, in 30% or more of T-LGLLs and CLPD-NKs, antibodies to HTLV-1 envelope proteins p21 and p24 are present in the absence of detectable HTLV-1 or HTLV-2 viral DNA. These findings suggest a role of infection by an HTLV-related virus in the development of some cases.[20,21] In T-LGLL, analysis of TCR β-chain variable region gene usage has revealed similar clonotypes among cases and within the oligoclonal expansions of individual cases and also disproportionate use of the TCR V-β 13.1, which is physiologically expanded in response to cytomegalovirus (CMV) infection. These data further implicate viral infection as a potential etiologic agent in T-LGLL.[22-24] CMV infection has also been shown to cause oligoclonal expansion of killer-cell immunoglobulin-like receptor (KIR)-expressing NK cells, and the activating form of the KIR appears important in physiologic responses to viral infection.[25] In CLPD-NK, a disproportionate number have KIR haplotypes that are rich in activating isoforms, and there is frequent expression of these activating KIRs and epigenetic inactivation of the inhibitory *KIR* genes.[26] These data suggest that viral infection may also be an important etiologic factor in the development of CLPD-NK.

T-LGLL after solid organ or hematopoietic stem cell transplantation could also be attributable to chronic viral stimulation. Alternatively, recipient cytotoxic T cells could undergo an uncontrolled clonal proliferation caused by alloantigen

stimulation in the setting of solid organ transplantation or donor cytotoxic T cells could clonally expand to self-antigen stimulation in patients with hematopoietic stem cell transplantation.[27] Other stimulants of cytotoxic T cells or NK cells may also play a role in T-LGLL and CLPD-NK development, as demonstrated by the association of these disorders with a variety of autoimmune diseases and other hematolymphoid neoplasms.[28,29]

T-LGLL and CLPD-NK are epidemiologically similar, representing less than 5% and less than 1% of all mature lymphoid leukemias, respectively.[30-33] These figures may not be indicative of the true prevalence of these diseases, however, as these diagnoses require both a high level of clinical suspicion and comprehensive laboratory evaluation; therefore, both may be underrecognized.

T-LGLL and CLPD-NK are diseases of adulthood, both with a median age of 60 years. Only sporadic cases are encountered in adolescents and young adults. Neither shows a predilection for gender, and neither is associated with Epstein-Barr virus (EBV) infection. Although some studies suggest that T-LGLL may be slightly more common in Asian populations, neither shows a strong geographic or ethnic predisposition.[28,34]

Clinical Features

Typically, patients present with signs or symptoms related to the disease-associated cytopenias (neutropenic infection or anemia-associated fatigue and dyspnea on exertion), and oftentimes the diagnosis is made during evaluation of asymptomatic lymphocytosis. Over time, more than 70% of patients with T-LGLL develop moderate-to-severe cytopenia(s) requiring treatment. Neutropenia is

the most common cytopenia, followed by anemia; transfusion-dependent anemia occurs in 10% to 30% of patients with T-LGLL. At diagnosis, anemia is often associated with neutropenia and/or thrombocytopenia. However, isolated anemia could be seen in a small subset of patients.[35] Less than 25% of patients have thrombocytopenia, almost always associated with other cytopenias.[29] Cytopenias are less frequent in CLPD-NK; therefore, treatment is less frequently required than in T-LGLL.[15,19,29,30,33,36,37]

In general, neither T-LGLL nor CLPD-NK is associated with B symptoms or significant clinical morbidity.[29,37] The most commonly encountered clinical sign in these disorders is organomegaly, particularly splenomegaly, which is present in approximately 20% to 30% of LGLLs.[30,32,36] Hepatomegaly has also been described in approximately 10% of T-LGL and CLPD-NK cases.[30,38,39] In these LGLL disorders, the organomegaly is presumably caused by organ infiltration, although when hepatomegaly is present, it is not usually associated with hepatic dysfunction. Mild lymphadenopathy may be seen in isolated cases. Prominent lymphadenopathy or involvement of extramedullary tissue sites is not typical, however, and, if present, should lead to the consideration of other possible diagnoses.

T-LGLL and CKPD-NK are strongly associated with both autoimmune phenomena and autoimmune disorders. Although the estimates vary among studies, it can be reliably stated that 30% of T-LGLLs and CLPD-NKs have abnormal serologic studies associated with immune activation such as polyclonal hypergammaglobulinemia, the presence of detectable rheumatoid factor, or a positive antinuclear antibody (ANA). Approximately 20%

of patients with T-LGLL have clinically diagnosed rheumatoid arthritis, but the association is less evident in patients with CLPD-NK.[36] A number of other autoimmune diseases are also associated with T-LGLL and CLPD-NK with lesser frequency, including systemic lupus erythematosus, chronic inflammatory bowel disease, and Sjögren syndrome.[28,29,36,40,41]

In addition to being associated with autoimmune disorders, T-LGLL and CLPD-NK also have the somewhat unusual feature of being associated with other clonal hematologic disorders, which are present in approximately 10% to 20% of cases. B-cell lymphoproliferative disorders and plasma cell proliferative disorders are most commonly described in this context.[42,43] Among the other hematologic diseases that have been identified in association with T-LGLL are myelodysplastic syndrome, acute myeloid leukemia, aplastic anemia, and paroxysmal nocturnal hemoglobinuria.[29,36,40,41,44,45]

Lastly, case reports have described T-LGLL being diagnosed in the setting of allogeneic renal and bone marrow transplantation.[27,46-48] As reactive CD8-positive T-cell expansions with limited clonal diversity and phenotypically similarities to T-LGLL have been reported after allogeneic transplantation,[49] it could be difficult to determine whether these cases represent bona fide lymphoproliferative disorders or distinct reactive processes of limited clonal diversity driven by interactions between host immunity and the allografted organ.

Morphology

T-LGLL and CLPD-NK have identical cytologic features in the peripheral blood, characteristically having small, minimally irregular nuclei and abundant pale-staining cytoplasm containing variably prominent azurophilic granules. In clinical practice, however, the degree of cytoplasmic enlargement and granulation in these LGL disorders varies considerably, and granulation of the lymphoid cells can be difficult to appreciate in some instances. For this reason, absolute granular lymphocyte counts are no longer included in the diagnostic criteria, although making the diagnosis without an obvious increase in granular lymphocytes requires both a high degree of clinical suspicion and comprehensive flow-cytometric immunophenotyping analysis[7] (**Table 30-1**).

T-LGLL and CLPD-NK cannot be distinguished from each other on cytologic grounds. Likewise, there is no singular morphologic feature in the peripheral blood that enables one to discriminate these disorders from an expansion of normal cytotoxic lymphocytes, although observing granular lymphocytes as part of a cytologic spectrum favors a reactive process. It should be noted that pronounced cytologic atypia and malignant cytology are not seen in either T-LGLL or CLPD-NK and, if present, should lead one to strongly consider the possibility of a leukemic phase of another more aggressive malignancy of cytotoxic lymphocytes, such as aggressive NK-cell leukemia.

In T-LGLL and CLPD-NK, it is difficult to recognize the abnormal lymphocytes in both bone marrow aspirate and biopsy.[17,18,50] In bone marrow aspirate, the cytoplasm is often contracted, obscuring the presence of granules. In hematoxylin and eosin (H&E) stained bone marrow clot sections and biopsies, the cytoplasmic granules are

not seen, which, in combination with the bland nuclear features of the cells and the characteristic interstitial pattern of infiltration, renders the cells virtually unidentifiable. For these reasons, histologic screening of bone marrow aspirates and biopsies is not useful when assessing for a potential T-LGLL or CLPD-NK diagnosis.

Table 30-1

A diagnosis of T-cell large granular lymphocytic leukemia (T-LGLL) or chronic lymphoproliferative disorder of NK cells (CLPD-NK) can be rendered if either three or more major criteria are present *or* at least two major criteria and two or more minor criteria are present.

* Flow-cytometric immunophenotyping is required to distinguish T-LGLL from CLPD-NK. If these studies are not performed and other diagnostic criteria for T-LGLL or CLPD-NK are satisfied, then a diagnosis of large granular lymphocytic (LGL) disorder, not further classifiable should be considered, particularly as the presence of clonal T-cell receptor gene rearrangements does not always demonstrate lineage fidelity. Also note that uniform CD16 expression and absence of CD5 expression can be seen in normal γδ T cells; however, these should not compose greater than 50% of the total T-cell pool. Uniform expression of KIR is *not* seen in normal γδ T cells and is a sign of aberrancy.

† The presence of sinusoidal cytotoxic lymphoid infiltrates that distend or disrupt the sinusoidal architecture or the uniform expression of multiple KIR antigens by the abnormal T cells should lead one to consider the possibility of hepatosplenic T-cell lymphoma.

Immunophenotype

Given the absence of distinctive cytologic or morphologic features, flow-cytometric immunophenotyping is a fundamental element of making a diagnosis of T-LGLL or CLPD-NK, particularly as this is the only way these disorders can be distinguished from each other.[14]

All T-LGLLs are CD3 positive by flow cytometry (usually expressed with TCRαβ heterodimer), and most are CD8 positive (**Fig. 30-1A**). The majority of T-LGLLs have abnormalities of pan–T-cell antigen expression, with 80% having either diminished expression or partial or complete loss of CD5; diminished or absent expression of CD7 is equally frequent. Diminished expression of CD2 is seen in less than 20% of cases, and abnormalities of CD3 expression are exceedingly rare in this disorder.[11,51]

Although abnormal expression of CD5 and CD7 are frequent in T-LGLL, neither is specific to this disease, and reactive CD8-positive T cells may show decreased expression of one or both.[52,53] For this reason, evaluation for aberrant co-expression of NK-cell–associated antigens, a pathognomic feature of T-LGLL, is critical for the diagnosis. Of the traditionally recognized NK-cell–associated antigens, CD16 and CD57 are most commonly expressed in T-LGLL, with CD16 expressed in 80% of cases and CD57 expressed in over 90% (**Fig. 30-1A**).[8,40] CD57 is also expressed by normal memory T cells; uniform homogeneous CD57 expression is distinct to T-LGLL, although this pattern is seen in less than half of cases.[11,54] CD56 expression is uncommon in T-LGLL and is present in less than 20% of cases. There are some reports of CD56-positive T-LGLL being associated with *STAT5b* mutations and aggressive disease, although these may represent peripheral blood involvement by other cytotoxic

T-cell malignancies that frequently are CD56 positive, such as hepatosplenic T-cell lymphoma.[55,56] Evaluation of TRBC1 expression by flow cytometry, as a surrogate for clonality, has made identification of a phenotypically aberrant T-cell population more straightforward (see this chapter's section titled Genetics and Molecular Findings).

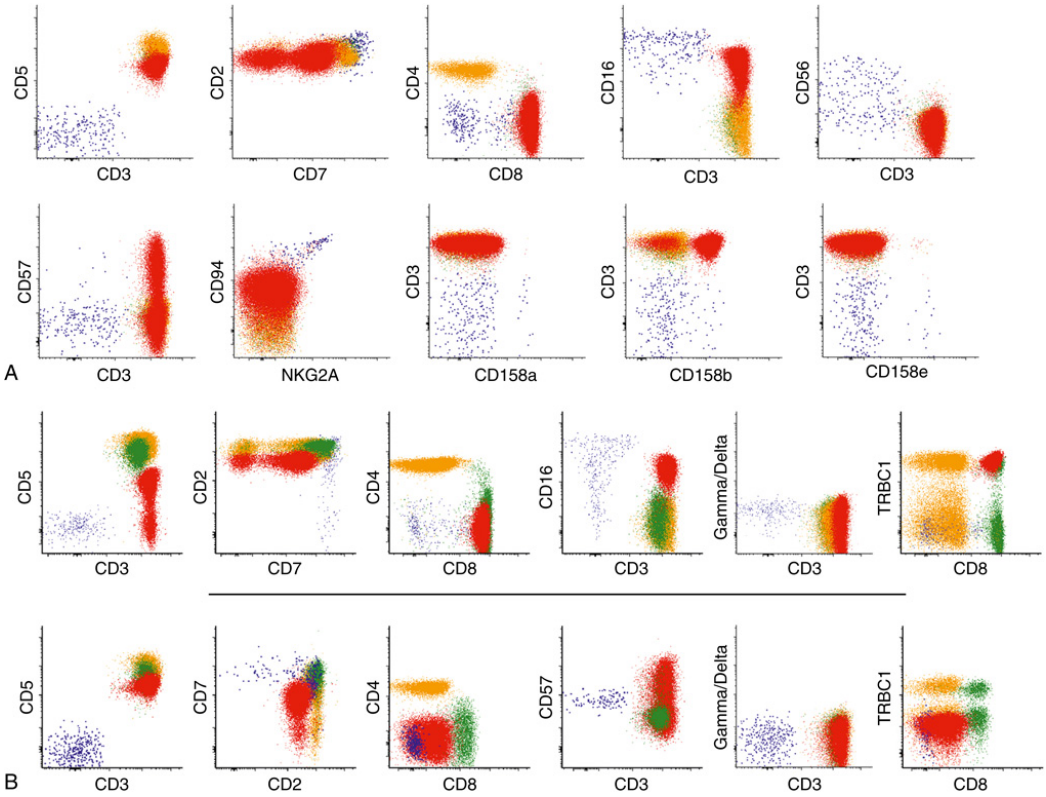

FIGURE 30-1 Flow cytometric immunophenotype for T-cell large granular lymphocytic leukemia (T-LGLL). The abnormal T cells are in *red*, normal CD4-positive T cells are in *orange*, normal CD8-positive T cells are in *green*, and normal natural killer (NK) cells are in *blue*. **A,** A representative T-LGLL case shows neoplastic cells are CD3-positive, CD2-positive, and CD8-positive T cells, with dim CD5 and partial CD7 expression. They express NK-cell–associated markers, such as CD16 (uniform), CD57 (partial), and CD94 (uniform). They uniformly express CD158b isoform, without CD158a or CD158e expression. **B,** Two T-LGLL cases reveal monotypic TRBC1

expression, characterized by being uniformly TRBC1-positive or TRBC1-negative. The background CD4-positive and CD8-positive T cells show polytypic TRBC1 expression.

Assessment of NCR expression by flow cytometry, particularly the KIRs CD158a, CD158b, and CD158e, can be an important aid in the diagnosis of T-LGLL.[11,16,57] Homogeneous expression of one or more KIR by the abnormal T cells is uniformly associated with T-cell clonality and is detected in approximately one-fourth of cases (**Fig. 30-1A**). Most KIR-positive T-LGLLs express a single isoform, with a strong tendency for CD158b, and in isolated cases (less than 10%), expression of two KIRs is seen. The uniform expression of all three of these KIRs is typical for hepatosplenic T-cell lymphoma, however, which helps distinguish it from T-LGLL in the clinical flow-cytometry laboratory.[58] CD94 is another NCR family member expressed by T-LGLL, often in combination with NKG2A, and is present in half of cases (**Fig. 30-1A**).

A minor subset of T-LGLL (<10%) are of γδ T-cell lineage.[10,59] Although these have features similar to their CD8-positive αβ counterpart, it should be noted that many of the phenotypic attributes associated with T-LGLL, including diminished CD5 expression and co-expression of CD16, are present in normal γδ T cells, particularly those expressing V-δ2.[60] Given this, evaluation of KIR is of particular utility in establishing an abnormal phenotype of γδ T cells and thereby confirming a γδ T-cell T-LGLL diagnosis. These studies should also be considered in other uncommon T-LGL variants such as CD4-positive, as the patterns of NK-antigen expression can both confirm the diagnosis and exclude other

potential considerations such as T-cell prolymphocytic leukemia, HTLV-1–associated lymphoproliferative disease, or other T-cell neoplasms.[9,61]

In clinical flow cytometry, expression of CD2, CD7, CD8, CD16, and CD56 by NK cells are routinely evaluated, and abnormalities of each of these are seen to varying degrees in CLPD-NK.[62] Normal NK cells express CD7 more brightly than normal T cells; in comparison, approximately half of CLPD-NKs have CD7 expression that is dimmer than that in normal T cells. Complete loss of CD7 expression may be seen in some CLPD-NKs, but this is uncommon. In normal peripheral blood, one-third of the NK cells are CD8 positive; in 20% of CLPD-NKs, there is abnormal uniform CD8 positivity. Absence of CD8 expression may also be observed, but given the relatively low level of CD8 expression by normal NK cells, it is difficult to use this as a feature to identify CLPD-NK with confidence. Diminished expression of CD2 is rarely present in CLPD-NK (by definition, these cells lack CD3), though rare CD5-positive CLPD-NKs have been described.[63] A CD5 expression in such a case would make it difficult to discern between a CD5-positive CLPD-NK and a CD3-negative T-LGLL. Cytoplasmic expression of CD3ε by flow cytometry may assist in distinguishing such two entities.[63] In approximately 50% of CLPD-NKs, CD56 expression is either completely or partially lost (**Fig. 30-2**). Interestingly, the phenotypes of CD56-positive and CD56-negative CLPD-NK cases differ, with the CD56-negative cases having brighter expression of CD16 and a tendency to be KIR positive and CD56-positive cases having slightly dimmer expression of CD16 (compared with CD56-negative cases) and tending to be KIR negative (**Fig. 30-2**).[64]

Analysis of NCR expression is even more useful in the evaluation of CLPD-NK than it is in the evaluation of T-LGLL. This is largely because, in healthy peripheral blood and bone marrow, the NK cells always express, to some degree, the KIRs CD158a, CD158b, and CD158e.[6,65] Therefore, unlike in T cells (which are not obligate KIR expressers), in NK-cells, both complete absence of KIR expression and homogeneous expression of KIR (single or multiple antigens) are abnormal, and one of these two abnormal patterns is present in almost all CLPD-NK cases.[16,57,66] As previously noted, homogeneous (i.e., restricted) KIR expression is preferentially seen in CD56-negative CLPD-NK, being present in 60% of such cases, whereas the majority of CD56-positive CLPD-NKs (70%) completely lack KIR expression. In 80% of KIR-positive CLPD-NKs, a single KIR is expressed, and most KIR-positive CLPD-NKs express CD158a for reasons that are unclear. In less than 10% of CLPD-NKs, the KIR expression pattern is indeterminate in regard to aberrancy in that it is positive but not with homogeneous expression of a single antigen or multiple antigens. Indeterminate KIR patterns are seen exclusively in cases with some degree of CD56 expression; in such cases, the CLPD-NK diagnosis hinges on other factors. The inhibitory heterodimeric MHC receptor complex CD94/NKG2A is always expressed by a proportion of the normal NK cells in the peripheral blood or bone marrow. Abnormally uniform, bright CD94/NKG2A expression is a distinctive feature of some CLPD-NK (**Fig. 30-2**).[67] This abnormality is present in nearly all CD56-positive CLPD-NKs and in approximately 50% of CD56-negative CLPD-NKs; it tends to occur in cases lacking KIR expression, although this finding and homogeneous KIR expression are not mutually exclusive.[64]

Because bone marrow involvement by these LGL disorders is not easily seen in routine histologic sections (**Fig. 30-3A**), bone marrow immunohistochemistry is required to detect the abnormal cells and is a valuable tool in confirming the diagnosis. The antigens of particular utility in this regard are CD8 and the cytotoxic granule proteins TIA-1 and granzyme B. Bone marrow immunohistochemistry using antibodies to these antigens allows for identification of the cytotoxic lymphocytes. An increase in bone marrow cytotoxic lymphocytes alone, however, is not sufficient to distinguish these disorders from reactive conditions. Rather, the essential diagnostic finding is the presence of linear arrays of cells (causes by intrasinusoidal infiltration) or large interstitial clusters (eight or more cells) (**Fig. 30-3A**).[17] The frequency with which one or both of these findings is present varies somewhat with the antibody tested, being detected in approximately 80% of cases by CD8 and TIA-1 immunohistochemistry and in approximately 50% of cases by granzyme B immunohistochemistry.[17] This finding may be present even in cases with low peripheral blood absolute granular lymphocyte counts (less than 1.0×10^9/L), although it is seen in only two-thirds of such cases.

When considering the use of immunohistochemistry to render a diagnosis of an LGL disorder, there are some important caveats to remember. Perhaps most important is that this methodology does not allow distinction of CLPD-NK and T-LGLL, as even the former may be CD3 positive by this method, and there is no immunohistochemical stain that is lineage-specific for either cytotoxic T cells or NK cells.[18,68] Furthermore, these stains can be challenging to interpret, as not all cases are CD8 positive or

granzyme B positive, and TIA-1 staining of lymphocytes in bone marrow may be difficult to interpret, as normal granulocytes also express this antigen. Therefore, the routine use of TIA-1 immunohistochemistry for this purpose requires bone marrow–specific antibody titration. Lastly, there are other disorders that have similar immunohistochemical features and patterns of bone marrow infiltration, chiefly hepatosplenic T-cell lymphoma.[69,70] Careful observation is helpful in this regard, as hepatosplenic T-cell lymphoma not only infiltrates in a sinusoidal pattern but also frequently distends and distorts the sinusoidal structure, whereas T-LGLL always percolates the sinusoids without causing abnormal distention.

Splenomegaly is attributable to T-LGLL infiltrates, demonstrated by a red pulp expansion of cytotoxic T cells expressing granzyme and TIA-1 (**Fig. 30-3B**). A focal intrasinusoidal infiltrate of cytotoxic T cells is evident (**Fig. 30-3B**). It could be challenging to distinguish liver involvement by T-LGLL, especially by γδ T-LGLL, from hepatosplenic T-cell lymphoma, because both have an intrasinusoidal infiltrate pattern. In contrast to highly atypical hepatosplenic T-cell lymphoma, T-LGLL is cytologically bland (**Fig. 30-3C**). In addition, hepatosplenic T-cell lymphoma has TIA-1 but lacks granzyme B expression, whereas T-LGLL usually expresses granzyme B.[70]

Genetics and Molecular Findings

The presence of T-cell clonality is a molecular genetic abnormality universally cited as a disease-defining feature of T-LGLL. T-cell clonality can be assessed by a variety of methods. Traditionally, most

commonly used in clinical practice are multiplexed polymerase chain reaction (PCR) amplification of TCR β and γ gene rearrangements (T-PCR) and flow-cytometric assessment of TCR β-chain V-region family usage (TCR V-β flow). It has been shown that incorporating TRBC1 into flow cytometric T panels provides a rapid, sensitive and cost-effective way to assess clonality of immunophenotypically distinct T-cell populations.[12,71] TRBC1 specifically recognizes one of two mutually exclusive TCR β-chain constant regions; therefore, T-LGLL cells either homogenously express (≥85% of cells) or do not express (≤15% of cells) TRBC1 (**Fig. 30-1B**). It has been demonstrated that TRBC1 assessment by flow cytometry was comparable to TCGR molecular study and superior to KIR flow cytometric analysis in establishing T-cell clonality in T-LGLL.[71] However, small T-cell clones with a T-LGLL immunophenotype may be detected in up to 20% of patients without other features of this disorder or other T-cell malignancy and therefore, as an isolated laboratory finding, must be interpreted with caution.[72]

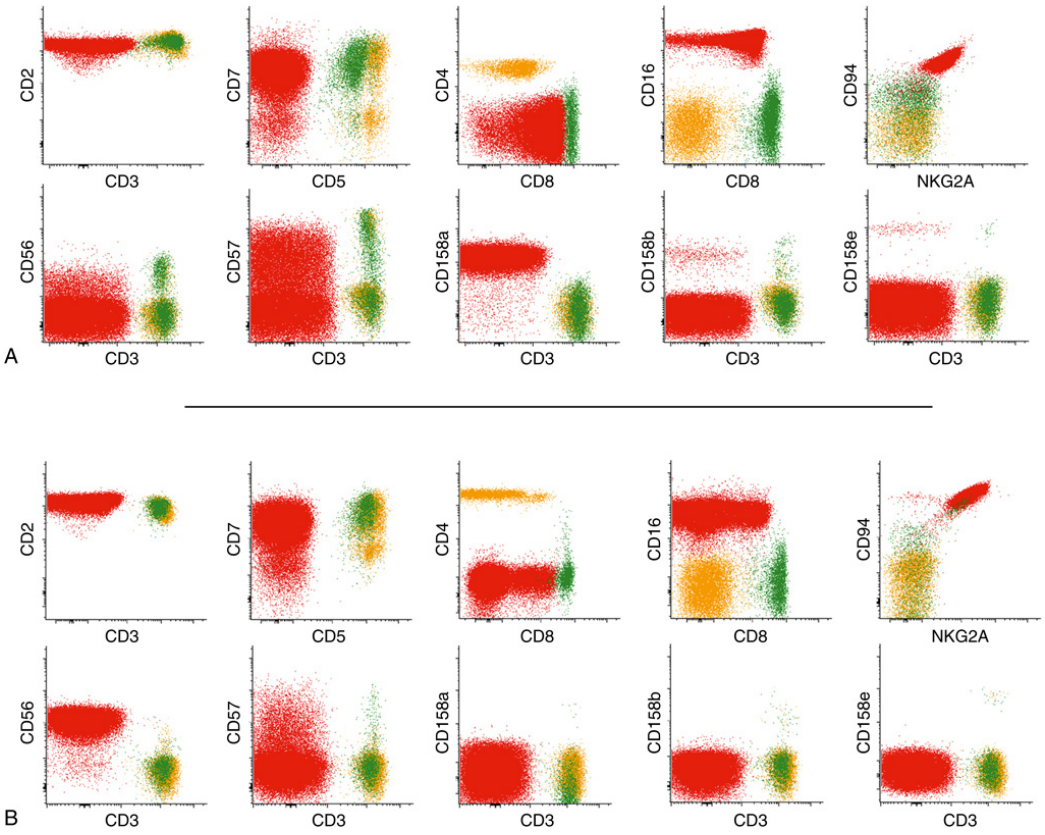

FIGURE 30-2 Flow cytometric immunophenotype for chronic lymphoproliferative disorder of NK cells (CLPD-NK). The abnormal natural killer (NK) cells are in *red*, normal CD4-positive T cells are in *orange*, and normal CD8-positive T cells are in *green*. **A,** CD56-negative CLPD-NK with brighter CD16 expression and CD158a restriction. **B,** CD56-positive CLPD-NK with dimmer CD16 expression and lack of KIR expression.

Although rare, co-existent T-cell and NK-cell clones or co-existent αβ and γδ T-cell clones have been identified in some LGLL cases.[73] Interestingly, LGLL-directed treatment may alter the proportions of

the concurrent clones.[73] Furthermore, serial analysis of individual T-LGLL cases has revealed that the distribution and proportions of the various "subclones" often change over time.[74] The co-existent clones may result from the emergence of LGLL clones recognizing different epitopes of the same chronic stimulant. Collectively, these data suggest that T-LGLL could be an oligoclonal disorder of cytotoxic T cells, and this may explain the inability to clearly demonstrate clonality in some cases. This oligoclonal nature of T-LGLL is important to keep in mind, as primary differential diagnostic considerations are reactive increases in cytotoxic T cells that may show similarly restricted subclone distributions.

For all of these reasons, practically speaking, a diagnosis of T-LGLL can neither be confirmed nor excluded based on the presence or absence of detectable T-cell clonality alone. TCR gene rearrangements play no role in the evaluation of potential CLPD-NK, as NK cells do not productively rearrange TCR (or other antigen receptor) genes. These limitations of TCR gene rearrangement analysis have spurred investigation of other potential genetic markers of disease clonality in LGL disorders.

Genome-wide mutational analysis has revealed such a marker with detection of an *STAT3* mutation in approximately 20% to 70% of both T-LGLL and CLPD-NK cases, depending on the assay sensitivity and the selection criteria.[19,75-83] A number of *STAT3* mutations have been identified in these disorders, preferentially occurring in exons 20 and 21, which encode the SRC homology 2 (SH2) domain of the protein, and also in the DNA-binding or coiled-coil domain.[80] These gain-of-function mutations mediate the constitutive dimerization and activation of STAT3 protein, which raises protein levels of

epigenetic regulators, increases global DNA methylation, and upregulates oxidative stress.[84] In T-LGLL, the presence of an *STAT3* mutation is associated with neutropenia, rheumatoid arthritis, a greater need for treatment, and methotrexate responsiveness.[19,75,76] The association of *STAT3* mutations and pure red cell aplasia (PRCA) is controversial: some studies show that *STAT3* mutations are frequent in LGLL with PRCA,[85-87] whereas others reveal *STAT3* mutations are invariably not seen in patients with LGLL and PRCA.[19,76] By multivariate analysis, *STAT3* mutations are independently associated to reduced overall survival in patients with LGLL.[33]

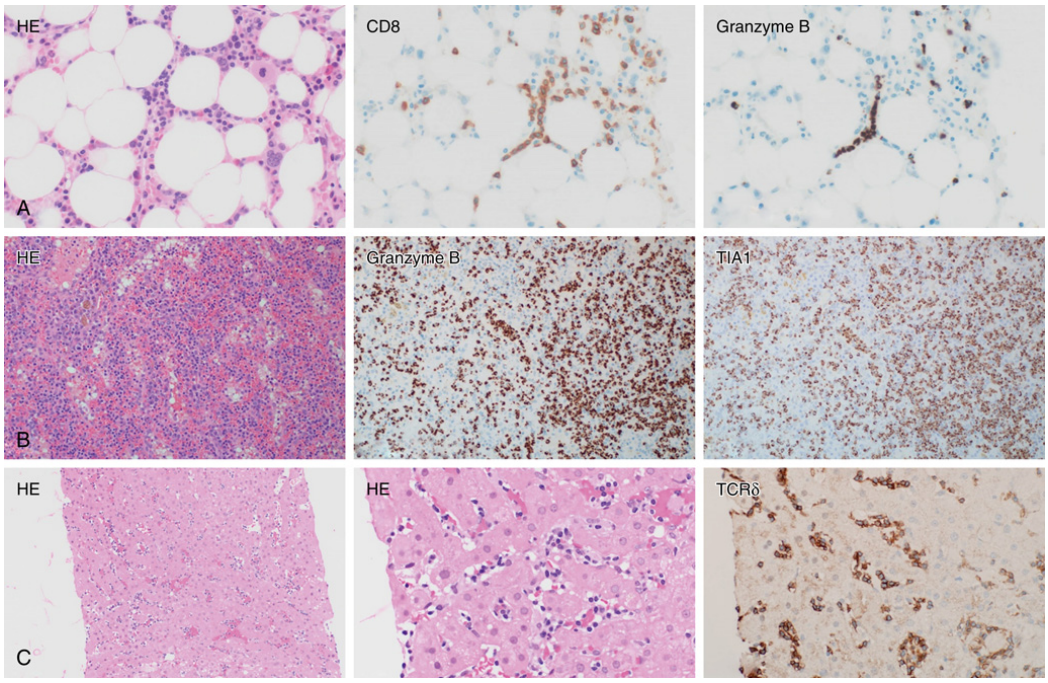

FIGURE 30-3 T-cell large granular lymphocytic leukemia (T-LGLL) with bone marrow, spleen, and liver involvement.A, Bone marrow histology usually does not reveal evident T-LGLL infiltrates. However, immunohistochemical studies show characteristic intrasinusoidal linear infiltrates of CD8-positive T cells expressing cytotoxic markers, such as granzyme B. **B,** T-LGLL predominantly involves red pulp of the spleen and focally involves intrasinusoidal regions, expressing both granzyme B and TIA1. **C,** T-LGLL infiltrates the liver sinusoids and expresses TCRγδ, making it difficult to distinguish from hepatosplenic T-cell lymphoma. T-LGLL usually has bland cytology and causes minimal architectural distortion.

Mutations of the *STAT5b* gene, mainly N642H and Y665F, have been identified in a minor subset of CD8-positive T-LGLL and CLPD-NK cases (<5%). These mutations occur only in cases lacking an *STAT3* mutation, and again effect the SH2 domain.[56,88] Subsequently, it has been found that *STAT5b* mutations are more prevalent in CD4-positive T-LGLL and γδ T-LGLL.[33,77,89] Although both N642H and Y665F mutations increase the transcriptional activity and tyrosine phosphorylation of *STAT5b,* N642H, but not Y665F, is associated with an aggressive and fatal clinical course in patients with CD8-positive T-LGLL and CLPD-NK. In contrast, patients with *STAT5b*-mutated CD4-positive T-LGLL are mostly asymptomatic with no or mild cytopenia, regardless of the mutation type.[33,56,88,89]

In addition to *STAT3* and *STAT5b* mutations, whole-exome sequencing from untreated patients with LGLL has revealed other recurrent mutations, in particular *TET2* mutations, which appear to be present in approximately 30% of CLPD-NK cases.[90,91] Other genetic abnormalities that have been identified in LGLL by this approach include mutations in transcriptional/epigenetic regulators and tumor suppressor and cell proliferation genes, such as *IGSF3, USH2A, TTN, CCT6P1, IGFN1, MUC4, TYPR1, ARL13B, FAT4, HRNR, KMT2D, NHS, ATN1,* and *PCLO*.[79] Interestingly, most *STAT*-mutation–negative patients harbor at least one of the "STAT-related component" genes, which connect to the MAPK-RAS-ERK pathway or IL-15 pathway, all known to be deregulated in LGLL.[79]

There have been isolated reports of cytogenetic abnormalities in both T-LGLL and CLPD-NK, including reports of abnormalities of chromosome 6 long arm (6q) and inversions and reciprocal

translocations involving the TCR gene loci on chromosomes 7 and 14.[92-94] No recurrent cytogenetic abnormalities have been identified in either disorder, however. Furthermore, cases with abnormal cytogenetics are preferentially found in the older literature, raising the possibility that these may have, in fact, been other conditions. Overall, it appears that cytogenetic abnormalities in what are currently recognized as T-LGLL and CLPD-NK are extraordinarily uncommon.

Postulated Cell of Origin and Pathogenesis

The phenotypes and patterns of gene expression of CD8-positive T-LGLL are all highly similar to normal memory CD8-positive T cells, and T-LGLL is clearly a disorder of this cell type.[22,95] Furthermore, a number of features, including abnormal distribution of TCR β-chain variable region use, are indicative of prior persistent cellular stimulation in T-LGLL.[96] CD4-positive T-LGLL expresses CD56, CD57, and varying levels of CD8 (CD8-negative or CD8-dim), suggesting these cases derive from a distinctive subset of circulating CD4-positive cytotoxic T cells that express NK-associated antigens, variably express CD8, and carry an antitumor/antiviral function.[9,66,89] The γδ T-LGLL co-expresses CD57 and cytotoxic antigens and has gene expression profiling similar to that of effector γδ T cells, indicating the normal effector γδ T cells are its cells of origin.[97]

In considering CLPD-NK, it is important to note that there are two normal mature NK-cell subsets (or types): NK1 cells with bright CD56, dim CD16, and low levels of NCR expression; and NK2 cells

with dim CD56, bright CD16, and high levels of NCR expression.[98] The NK1 cells function primarily through cytokine production, whereas the NK2 cells function through cellular cytotoxicity. NK1 cells are converted to NK2 cells through stimulation and exposure to cytokines such as IL-12. In CLPD-NK, it appears that the CD56-positive and CD56-negative cases correspond to the normal NK1 and NK2 NK-cell subsets, respectively. Interestingly, cytopenias and other clinical features typically seen in T-LGLL are much more common in the CD56-negative CLPD-NK compared with CD56-positive cases. Hence, it appears that chronic cellular stimulation is a critical first pathogenetic event in both T-LGLL and CLPD-NK, although the precise nature of the stimuli is still unclear.

If ongoing cellular stimulation with selective enrichment of certain clonotypes is a critical first step in the pathogenesis of these granular lymphocytic disorders, then the equally critical second step is the ability of these clones to survive through circumvention of normal activation-induced cell death and undergo an uncontrolled proliferation. In T-LGLL, the ability of the abnormal cells to survive may be in part attributable to NCR expression. During the course of normal cytotoxic T-cell responses, there is physiologic restriction of the T-cell repertoire and a commensurate increase in NCR expression by the cytotoxic T cells. The NCR expression by these T cells serves a dual purpose, both preventing inappropriate autoreactivity and prolonging cell survival through inhibiting activation-induced cell death.[99,100] T-LGLL, by comparison, appears to be a distortion of this normal immune response, with pronounced oligoclonal or clonal T-cell repertoire restriction and abnormally high levels of NK-associated antigen expression, including NCR. In

NK cells, there are varying hypotheses regarding the acquisition of NCR and how it relates to increased cytotoxic function; therefore, the connection between NCR expression and CLPD-NK pathogenesis is less clear.[6,101] The propensity of CLPD-NK to express the activating KIR isoforms and to epigenetically silence the expression of the inhibitory isoforms may be indicative of a role for these receptors in disease development.[57,102,103] Overall, there is a growing body of evidence suggesting that, in CLPD-NK, the interplay between NK cells and dendritic cells, regulated through NCR and MHC interactions, may be a primary contributing factor to the development of this condition.[104]

There is also a wealth of data indicating that perturbations of cellular signaling cascades are an important facet of the abnormal survivability of the cells in T-LGLL and CLPD-NK. The JAK-STAT pathway appears to be at the center of these perturbations. Constitutive activation of STAT3 appears to play an essential role in the pathogenesis of LGLL, because almost all cases have constitutive activation of the STAT3 pathway, which promotes cell survival and proliferation. The inhibition of STAT3 signaling restores the apoptosis of LGLL cells by reducing BCL2-family protein Mcl-1.[105] Constitutive activation of STAT3 could be caused by the gain of function mutations in STAT3 or somatic mutations in *STAT3* responsive genes.[88] In addition, increased proinflammatory cytokine IL-6 or downregulated suppressor of cytokine signaling to 3 (SOCS3) leads to constitutive activation of STAT3 in *STAT3*-unmutated patients.[106] Similar to *STAT3, STAT5b* mutation-induced STAT5b activation also promotes cell survival and proliferation. It has been demonstrated that IL-15 and IL-15Rα are elevated in patients with

LGLL, inducing the downstream activation of the JAK1/STAT3 and JAK3/STAT5 pathway.[107-109] Abnormalities in other pathways that regulate cell survival, primarily through modulation of BCL2 family proteins, have also been identified in patients with LGLL, including the RAS/MAPK, PI3K/AKT, NF-κB and sphingolipid pathways.[79,110-116]

Lastly, the ability of the abnormal granular lymphocytes to suppress or destroy normal hematopoiesis is the most clinically relevant component of the disease process. In spite of this, the exact mechanism by which this occurs has yet to be defined. There have been a number of studies implicating Fas-Fas ligand interactions through the elevated soluble Fas.[77,117] In addition, there are published cases of both T-LGLL and CLPD-NK in which the ability of the abnormal cells to kill normal human hematopoietic cells has been demonstrated.[118,119] Therefore, it appears that the cytopathic effects of these disorders may be exerted through both humoral and cellular means.

Clinical Management and Prognosis

From a clinical perspective, the same management approach is used for T-LGLL and CLPD-NK; in both disorders, the decision to treat is primarily predicated on the presence or absence of disease-associated cytopenias.[28,29,40] If cytopenias are absent, the disorder may be observed without disease-specific therapeutic intervention. However, therapy is indicated if the patient has moderate-to-profound neutropenia associated with recurrent infections or symptomatic or transfusion-dependent anemia. Therapy typically consists of methotrexate, cyclophosphamide, or cyclosporin, either

as single agents or in combination with corticosteroids during the initiation of therapy. Responsiveness to therapy is assessed by improvement of symptoms and complete blood counts, which should occur within the first 6 months of treatment. The overall response rate (complete response and partial response) for the single-agent therapy varies among different studies, ranging from 20% to 80%.[28,30,120,121] It has been reported that patients with LGLL with *STAT3* mutations are more likely to respond to methotrexate treatment.[75,120] In cases of failure of primary therapy, a switch to methotrexate, cyclophosphamide, or cyclosporin should be considered.

Splenectomy may be performed in patients with symptomatic splenomegaly and associated refractory cytopenia, but a proven benefit with a durable response is controversial.[30,122] A small number of studies suggest efficacy of purine analogs (e.g., fludarabine) in the treatment of T-LGLL.[123] Immunotherapy, such as anti-CD52 monoclonal antibody therapy with alemtuzumab and anti-CD20 with rituximab, has been used, although further studies are needed for a clinically demonstrable response.[124-126] Inhibitors for IL-15 or the JAK/STAT pathway could be a good therapeutic option in patients with LGLL.[29,127,128]

The avoidance of therapy-related complications is paramount in T-LGLL and CLPD-NK, as both are indolent disorders typically with a prolonged disease course and minimal morbidity and mortality. The reported proportion of patients requiring therapy at some point for their disease varies, although large series with extended follow-up indicate that the majority of patients with T-LGLL will eventually develop cytopenias requiring treatment. As previously noted, it

appears the majority of CD56-negative CLPD-NKs require therapy, whereas the majority of CD56-positive cases do not. Given the paucity of large CLPD-NK studies, however, it is difficult to precisely ascertain how many patients with CLPD-NK will develop the need for treatment over time.

Although the vast majority of cases are indolent, there are sporadic reports of T-LGLL and CLPD-NK exhibiting aggressive clinical behavior, similar to other cytotoxic NK/T-cell malignancies. In T-LGLL, this has been associated with a CD56-positive phenotype, raising the possibility that these may, in fact, be other T-cell disorders that more frequently express this antigen, such as hepatosplenic T-cell lymphoma.[58,70] Likewise, aggressive CLPD-NKs are more common in older adults, suggesting that many were, in fact, other disorders that were subsequently recognized, such as aggressive NK-cell leukemia. Scarcely, transformation of an indolent LGLL to an aggressive T-cell or NK-cell lymphoma/leukemia has been reported.[129-132] It appears that highly malignant T-LGLL and CLPD-NK cases, either at diagnosis or as a feature of disease progression, are extraordinarily rare and difficult to predict based on recognized pathologic features.

Differential Diagnosis

The primary differential diagnostic considerations for both T-LGLL and CLPD-NK are reactive cytotoxic T-cell and NK-cell expansions at one end of the spectrum and highly aggressive cytotoxic T-cell and NK-cell neoplasms that can involve the peripheral blood, such as hepatosplenic T-cell lymphoma and extranodal NK/T-cell lymphoma, at the other end (**Table 30-2**). From a clinical

perspective, distinguishing these indolent granular lymphoproliferative disorders from these more aggressive diseases is relatively straightforward. From the pathologist's perspective, this distinction can be much more challenging, as the cytology of these malignancies does not always correlate with their clinical aggressiveness. Destructive tissue infiltration and clonal cytogenetic abnormalities are not a feature of T-LGLL or CLPD-NK, and, if present, should lead to other diagnostic considerations. Phenotypically, the expression of multiple KIR antigens by the abnormal cells can help distinguish hepatosplenic T-cell lymphoma from T-LGLL. The flow-cytometric immunophenotype of aggressive NK-cell leukemias and lymphomas have not been well characterized, and therefore the phenotypic features that may distinguish these from CLPD-NK are not evident. Assessing for EBV positivity in tissue sections is critical, however, as neither T-LGLL nor CLPD-NK is EBV associated, whereas almost all cases of aggressive NK-cell leukemia and extranodal NK/T-cell lymphoma are.

Table 30-2

BM, Bone marrow; *PB,* peripheral blood; *T-CUS,* T-cell clones of uncertain significance; *T-LGLL,* T-cell large granular lymphocytic leukemia.

Distinguishing T-LGLL and CLPD-NK from reactive T-cell and NK-cell expansions is more problematic, as these LGL disorders are derived from cytotoxic immune responses. It has been reported that T-cell clones with uncertain significance (T-CUS) are found in approximately 20% of patients without T-cell neoplasm, indicating T-CUS could be a physiologic expansion of an immunodominant

clone. T-CUS is mainly CD8-positive T cells with an immunophenotype closely resembling that of T-LGLL but a much smaller clone size.[72] The natural history of T-CUS is not clear at this point, but the extensive workup of small CD8-positive T-cell clones (<15% of lymphocytes or <500 cells/μL) with an immunophenotype of T-LGLL is likely not warranted.[71] However, in cases with increased granular lymphocytes and unexplained cytopenias, extensive evaluation for, and exclusion of, other potential causes and demonstration of persistence of the clinical features may be required to distinguish between the reactive NK/T-cell expansions and bona fide T-LGLL/CLPD-NK.

Pearls and Pitfalls

Pearls

- T-LGLL and CLPD-NK can only be distinguished from each other by flow-cytometric immunophenotyping. Their peripheral blood and bone marrow morphologies are identical. Both harbor *STAT3/STAT5b* mutations.
- The clinical management of T-LGLL and CLPD-NK are the same; therefore, distinguishing between them is not required for treatment to be initiated.
- Bone marrow immunohistochemistry is required to detect marrow involvement by lymphoproliferative disorders of granular lymphocytes.

- An absolute increase in peripheral blood granular lymphocytes is not present in all cases of T-LGLL or CLPD-NK, although the granular lymphocytes typically account for more than 50% of all lymphoid cells.
- Distention and/or distortion of bone marrow sinusoids and expression of multiple KIRs are not typical of T-LGLL or CLPD-NK and suggest diagnosis of an aggressive disease such as hepatosplenic T-cell lymphoma.

Pitfalls

- A reactive increase in granular lymphocytes can be seen in a number of conditions associated with cytopenias, including myelodysplasia and viral infection.
- Clonal TCR gene rearrangements can be detected in a variety of settings associated with restriction of the T-cell repertoire, including viral infection, after allogeneic organ transplantation, and normal aging. Therefore, these have poor diagnostic specificity in the absence of pathologic features supporting a T-LGLL diagnosis.
- Small T-cell and NK-cell populations with phenotypic attributes similar to those of T-LGLL and CLPD-NK, respectively, can be detected in healthy, asymptomatic adults.
- T-LGLL and hepatosplenic T-cell lymphoma can have similar peripheral blood and bone marrow manifestations.

- Clinical Features
- Morphology
- Immunophenotype
- Genetics and Molecular Findings
- Postulated Cell of Origin
- Clinical Course
- Treatment

DIFFERENTIAL DIAGNOSIS

Definition

T-cell prolymphocytic leukemia (T-PLL) is an aggressive disease characterized by a proliferation of small to medium-sized lymphocytes with a postthymic phenotype usually involving the blood, bone marrow, lymph nodes, spleen, and skin.[1-3] This leukemia was first described by Catovsky and colleagues in reference to a patient who presented with cytologic features similar to B-cell prolymphocytic leukemia (B-PLL), but the cells were shown to bind sheep erythrocytes (E-rosette positive).[4] In 1986, Matutes and coworkers published a more detailed report comparing morphologic and clinical characteristics of 29 T-PLL and 33 B-PLL cases and defining the immunophenotype as consistent with mature T cells.[5] In 1987, the same group reported an association of T-PLL with inv(14)(q11q32) and trisomy for 8q.[6]

Consensus Criteria For Diagnosis

The T-PLL International Study Group published in 2019 standardized criteria for diagnosis, treatment indications, and evaluation of response in patients with T-PLL.[7] Three major and four minor criteria were defined:

Major Criteria

1. >5 × 10^9/L cells of T-PLL phenotype in peripheral blood or bone marrow

2. T-cell clonality (by polymerase chain reaction [PCR] for TRB/TRG, or by flow cytometry)
3. Abnormalities of 14q32 or Xq28 OR expression of *TCL1A/B* or *MTCP1*

Minor Criteria

1. Abnormalities involving chromosome 11 (11q22.3; *ATM*)
2. Abnormalities in chromosome 8: idic(8)(p11), t(8;8), trisomy 8q
3. Abnormalities in chromosomes 5, 12, 13, or 22 or complex karyotype
4. Involvement of T-PLL specific site (e.g., splenomegaly, effusions)

The T-PLL diagnosis can be established if all major criteria (met in 90% of cases) or two major and one minor criteria (TCL1-family negative T-PLL) are met.

These criteria are generally followed by the published 2022 International Consensus Classification on Mature Lymphoid Neoplasms[8] and proposed World Health Organization (WHO) 5th edition on Hematolymphoid Neoplasms.[9]

Epidemiology

T-PLL represents approximately 2% to 3% of all T-cell disorders but accounts for up to one-third of mature T-cell malignancies with a leukemic presentation.[10,11] This leukemia occurs mainly in older adults (median age 61 years) and more often in men (male-to-female ratio approximately 2:1).[11] An increased frequency has been found in

patients with ataxia telangiectasia, an autosomal recessive disorder caused by loss of heterozygosity at 11q22-23 (mutated *ATM* gene).[12] Patients with ataxia telangiectasia develop T-PLL at a younger age (26 to 43 years).[13] A single sporadic pediatric case has been reported.[14]

Clinical Features

Most T-PLL patients present with general symptoms: sweating, malaise, weight loss, or fever.[11,15-17] The median duration of symptoms is 2 months before diagnosis. In most patients, a high white blood cell (WBC) count (>100 × 10^9/L in 72%) is found, sometimes with extreme hyperlymphocytosis, splenomegaly (79%), lymphadenopathy (46%), and enlarged liver (39%).[15,18-20] Rare aleukemic cases have been described.[21] One-fourth of patients have skin lesions at diagnosis, mainly maculopapular rash, nodules, or (more seldom) erythroderma.[15,22-24] In 15% to 30% of patients, mainly those with high WBC counts, serous effusions are found at diagnosis or may also develop later in the course of the disease.[15,16,18] Central nervous system involvement is rare.[15,18] Thirty percent to 50% of patients present with anemia (hemoglobin <100 g/L), thrombocytopenia (<100 × 10^9/L), or both.[11,15,18] Usually, there is no neutropenia or monocytopenia. Hyperuricemia and increased levels of lactate dehydrogenase are common. Other liver function tests may be mildly elevated, whereas serum immunoglobulin and renal biochemistry are normal.[15,18] Although serum from most Western patients with T-PLL has tested negative for human T-lymphotropic virus (HTLV) types 1 and 2, in some Japanese patients, DNA samples contained an HTLV-1 Tax

sequence.[25,26] A single case of T-PLL positive for Epstein-Barr virus has been reported.[27]

Morphology

Typical T-PLL cells in the peripheral blood are medium-sized lymphocytes with a high nuclear-to-cytoplasmic ratio and deeply basophilic cytoplasm without granules, often showing protrusions (**Box 31-1**; **Fig. 31-1A**). Ultrastructural studies show numerous ribosomes, polyribosomes, and profiles of rough endoplasmic reticulum, accounting for the cytoplasmic basophilia.[5,15,18,23] Nuclei are often irregular, with numerous short indentations, and they have moderately condensed chromatin and prominent nucleoli. Cytochemical staining for α-naphthyl-acetate esterase shows a characteristic dotlike pattern.[28]

In approximately 20% of cases, the leukemic cells are smaller, the nuclei are round, and the nucleoli cannot be readily seen by light microscopy (**Fig. 31-1B**), although they are easily detected by electron microscopy.[5] In some publications, these cases are called a *small cell variant* of T-PLL. Because the clinical presentation and cytogenetic features are similar, both variants of T-PLL probably belong in the same category.[16,29] Most cases in publications on T-cell chronic lymphocytic leukemia show a typical morphology and immunophenotype and chromosomal changes corresponding to the small cell variant of T-PLL.[30-33] In rare cases, polylobated nuclei are noted, similar to those in adult T-cell leukemia/lymphoma. In other cases, cerebriform nuclei, as seen in Sézary syndrome, are described.[23,34]

In bone marrow trephine biopsies, there is usually increased cellularity, which varies from slightly hypercellular to “packed” bone marrow. Patterns of infiltration may be nodular or interstitial, with leukemic cells constituting only part of the bone marrow cellularity, or diffuse infiltration with a dominance of leukemic cells (**Fig. 31-1C**).[28] In some cases, there is discordance between the blood and bone marrow involvement, and patients with marked leukocytosis may have a much lower level of marrow involvement. There is often slight fibrosis, shown by an increase in the density of reticulin fibers. On trephine sections, T-PLL cells are small to medium-sized and relatively round, making them difficult to differentiate from the cells of other chronic lymphoproliferative disorders. Characteristic cytologic features are more noticeable on bone marrow imprints or smears that show infiltration of cells like those in peripheral blood.[35]

Box 31-1 Major Features of T-Cell Prolymphocytic Leukemia

NK, Natural killer; *TCR,* T-cell receptor; *TIA-1,* T-cell-restricted intracellular antigen-1.

Morphology

- Peripheral blood cytomorphology
- Common variant: intermediate-sized lymphocyte with round or irregular nuclear contour, moderately condensed chromatin, prominent central nucleoli, abundant basophilic cytoplasm with protrusions, no granules

- Small cell variant: small lymphocyte with round to mildly irregular nucleus, clumped chromatin with inconspicuous nucleolus, scant basophilic cytoplasm
- Bone marrow histomorphology: diffuse, solid sheets of lymphocytes effacing normal bone marrow architecture; less frequently, diffuse interstitial or nodular infiltrates with partially preserved architecture

Immunophenotype

- $CD2^+$, $CD3^+$, $CD5^+$; usually strongly $CD7^+$; TCRαβ
- $CD4^+/CD8^-$ (most common); $CD4^+/CD8^+$ or $CD4^-/CD8^+$ (less frequent)
- $TCL1^+$, $CD26^+$ (usually)
- NK-associated marker (CD16, CD56, CD57) negative
- Cytotoxic granule molecule (TIA-1, granzyme B) negative

Genetics

- TRB, TRG genes rearranged
- Rearrangement of *TCL1*αβ locus in inv(14)(q11q32.1) or t(14;14)(q11;q32.1)
- Rearrangement of *MTCP1* in t(X;14)(28;q11)
- Trisomy 8 or iso8q
- Mutations in *ATM* at 11q23
- Gain of function mutations involving *IL2RG, JAK1/3,* and *STAT5B*

- Deleterious mutations affecting *EZH2, FBXW10,* and *CHEK2*

Lymph nodes show a diffuse infiltration of leukemic cells. These cells are seen mostly in interfollicular areas, but they may also completely replace the normal architecture (**Fig. 31-2A**). Residual germinal centers may be present.[36] In paraffin sections, leukemic cells are medium-sized and rather monomorphic. Mitotic figures are easily identified, and Ki-67 (MIB-1) staining shows a high fraction of proliferating cells (usually 30%–60%) (**Fig. 31-2B**). Typical features, including prominent nucleoli and abundant cytoplasm, are more easily appreciated in imprints or fine-needle aspirates from the lymph nodes (**Fig. 31-2C**).

Osuji and associates described morphologic features of splenic involvement by T-PLL.[37] The spleen is often grossly enlarged. T-PLL cells infiltrate the red pulp—both sinusoids and cords—and the white pulp shows signs of disruption caused by the infiltration of leukemic cells into the follicles (**Fig. 31-2D**). The sinus pulp cord architecture is not distorted. Angioinvasion and infiltration of fibrous trabeculae are prominent. Leukemic cells infiltrate through the splenic capsule and into perisplenic fat tissue. In the liver, T-PLL infiltrates are usually confined to portal tracts, with variable portal tract expansion and sinusoidal involvement.[36] T-PLL cells can be seen within the blood vessels of portal tracts.

Skin infiltrates are usually confined to the dermis (**Fig. 31-2E**). The infiltrates sometimes extend into the subcutaneous adipose tissue. Lymphoepidermotropism or a subcutaneous mass may develop.[22,38,39] Infiltrates are usually present around capillaries and skin appendages. There is a variable degree of stromal edema surrounding the blood vessels, with minimal endothelial damage and

few extravasated erythrocytes. In most skin infiltrates, round nuclei are seen. Only rare cases with Sézary-like cells have been found. Progression to high-grade cutaneous CD30-positive large-cell lymphoma, with chromosomal changes identical to those seen in blood T-PLL cells, has been described.[40] Rare cases of ocular involvement have been described presenting with pan-uveitis, retinal detachment, or perivascular conjunctival involvement.[41,42] Reports on the morphology of other extramedullary sites involved by T-PLL are rare in the literature.[36]

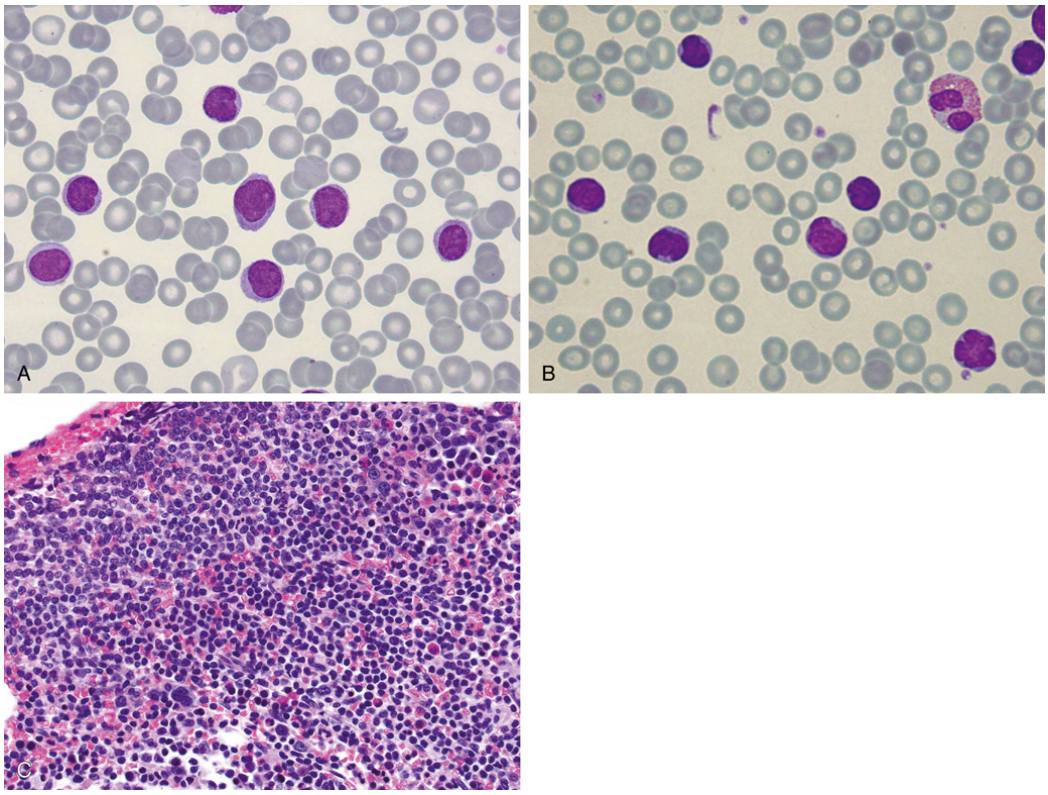

FIGURE 31-1 Peripheral blood lymphocytes in a typical case of T-cell prolymphocytic leukemia **(A)** and a small cell variant with moderately irregular nuclear contours **(B). C,** Bone marrow effacement by a diffuse infiltrate of T-cell prolymphocytic leukemia.

Immunophenotype

By flow cytometry, almost all T-PLL cases are positive for CD7, usually with high intensity. In cases with low or negative CD7, genetic data should be obtained before a diagnosis of T-PLL is considered. Leukemic cells are positive for cytoplasmic CD3, but membrane CD3 is negative in 20% of cases. In most cases, there is a strong expression of CD45, but rare CD45-negative or only weakly

CD45-positive cases do occur. The leukemic cells are usually positive for CD2, CD5, CD43, and CD26. Most cases show one homogeneous abnormal population, but several subsets were noted in some cases. Approximately 60% of cases display a CD4-positive CD8-negative phenotype, but a CD4-positive CD8-positive phenotype (15%–25%) or a CD4-negative CD8-positive phenotype (10%–15%) is also found (**Fig. 31-3**).[15-18,43] In rare cases, a combination of negative membrane CD3, lower-than-normal CD45, and co-expression of CD4/CD8 may bring a differential diagnosis of T-cell lymphoblastic leukemia-lymphoma. However, T-PLL cases do not express terminal deoxynucleotidyl transferase (TdT), CD1a, CD34, or CD10. CD34 and myeloid markers are not seen, except for CD117, which was noted in rare cases.[43] There is no expression of natural killer (NK)-cell markers (CD56, CD57, CD16) or of the cytotoxic marker TIA-1 (T-cell-restricted intracellular antigen-1), even in CD8-positive cases. However, perforin expression is noted in some cases. T-cell activation markers such as CD25, CD38, and human leukocyte antigen (HLA)-DR are variably expressed.[15-18,43] Two cases of CD103-positive T-PLL have been described, but data on CD103 expression in larger series are not available.[44]

TCL1 protein is detected by immunohistochemistry in 60% to 80% of cases (**Fig. 31-4**).[36,37,45] CD30, TRAP, anaplastic lymphoma kinase-1 (ALK-1), BCL6, and BCL3 are negative.[17,18,37,46] Data on BCL2 expression are not available in the literature, but our experience suggests that BCL2 is strongly positive (**Fig. 31-2F**). There are no larger published studies on ZAP-70 expression in T-PLL, but some cases may be positive.[47] In a small studied series of 20 patients with T-PLL, six were found to be positive for S100.[48]

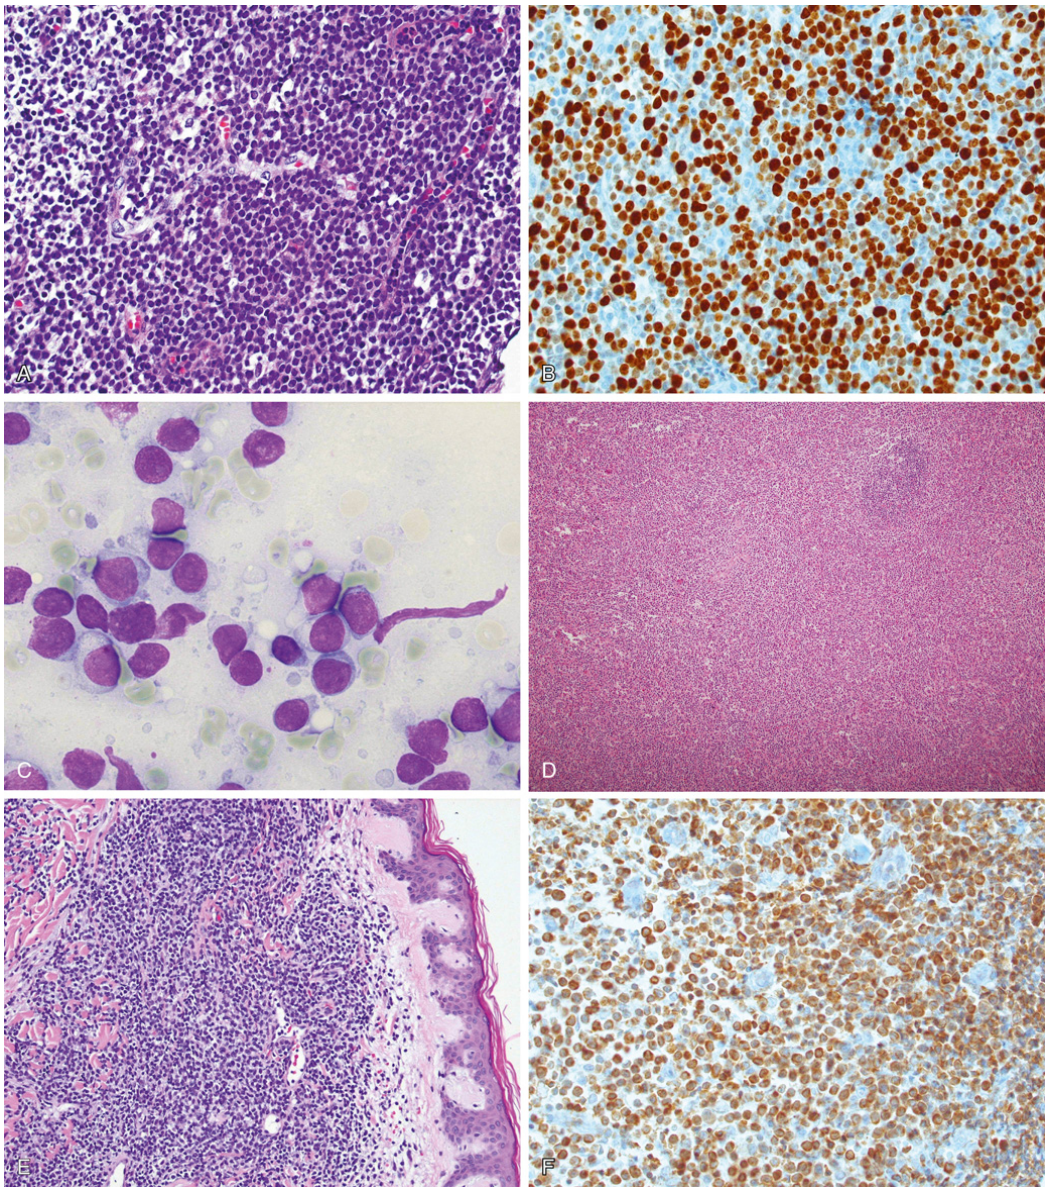

FIGURE 31-2 **A,** Core needle biopsy of a lymph node shows a diffuse infiltrate of T-cell prolymphocytic leukemia (T-PLL). **B,** Ki-67 immunostain shows high proliferative activity of T-PLL (estimated at 60%). **C,** Fine-needle aspirate smear from a lymph node shows prominent nucleoli and abundant cytoplasm of neoplastic cells. **D,** Effacement of splenic red

pulp by diffuse T-PLL infiltrate. **E,** Heavy infiltrate in the skin involves primarily the dermis and subcutaneous soft tissues, with characteristic sparing of the epidermal layer. **F,** BCL2 shows uniformly strong expression in neoplastic cells of T-PLL.

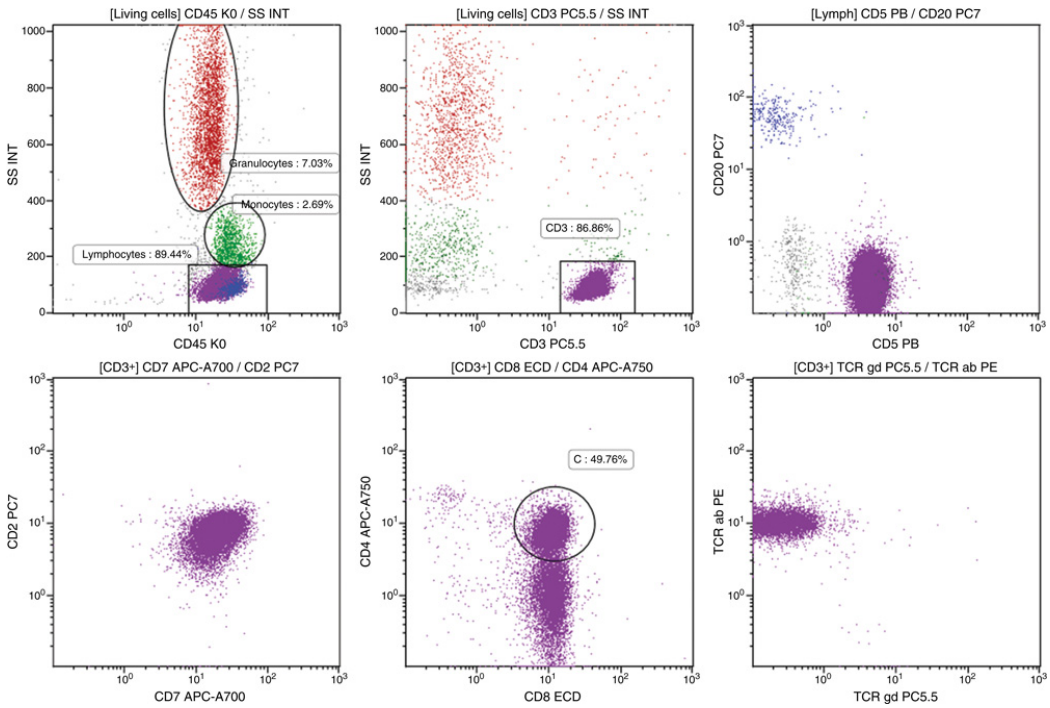

FIGURE 31-3 Flow cytometry results in T-cell prolymphocytic leukemia (T-PLL). Ten-color flow cytometry was used as described in the literature[91] on a blood sample from a 55-year-old male patient. CD45/SSC plot *(upper-left panel)* shows composition of the sample with 7% granulocytes, 2.7% monocytes, and 89% lymphocytes. The CD3-positive T cells *(violet dots)* account for 89.6% of cells in the blood and are of similar scatter characteristics as B cells (CD20-positive *blue dots*). CD3-positive cells are also positive for CD2, CD7, CD5, CD8, and TCRαβ with an aberrant phenotype of CD8bright^{+}, CD4dim$^{+/-}$ in 49% of cells. CD25, CD56, CD57, CD30, CD1a, and CD10 were negative in the leukemic population *(not shown)*.

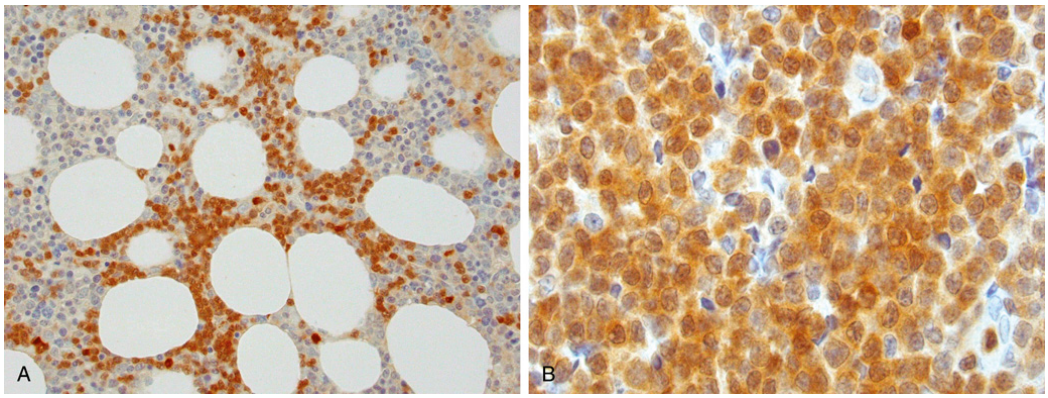

FIGURE 31-4 Strong nuclear and cytoplasmic staining is seen with anti-TCL1 antibody in bone marrow **(A)** and lymph node **(B)** infiltrated by T-cell prolymphocytic leukemia. Courtesy Dr. Elizabeth Hyjek, Department of Pathology, University of Chicago.

CD52 is found on T-PLL cells at a higher density than on normal B and T lymphocytes or in B-cell chronic lymphocytic leukemia, which may be the reason for the favorable response to treatment with anti-CD52.[49]

Genetics and Molecular Findings

Both TRA and TRB genes are rearranged in most cases.[16,50] However, some cases with only TRG/TRD rearrangement have been described.[36,51,52] Pathologic restriction of the variable (V) region of β-chain use was detected by a broad array of antibodies and flow cytometry.[53]

Cytogenetic studies in T-PLL have found recurrent chromosomal abnormalities. In 90% of cases, the Xq28 *(MTCP1)* or 14q32.1 (*TCL1A* and *TCL1B*) regions were involved in translocations or

inversions with TCRA/D at 14q11.[6,54-57] *TCL1A* and *MTCP1* have partial amino acid or nucleotide sequence similarity (41% identical and 61% similar).[58] A third member of this family, *TCL1B,* located at 14q32.1, also shows similarities to *TCL1A* in structure and expression.[59] In T-PLL, all three genes are activated and overexpressed by juxtaposition to the αδ locus at 14q11. High-density single-nucleotide polymorphism (SNP)-array analysis detected frequent copy number alterations in *TCL* oncogenes.[60] *TCL1A* encodes for a predominantly cytoplasmic protein of 14 kD that is also found in small quantities in the nuclei of lymphoid cells.[61] The TCL1 protein binds to the D_3 phosphoinositide-regulated kinase AKT1, enhancing its activity and promoting its transport to the nucleus.[59] In T-PLL, T-cell receptor (TCR) stimulation leads to the rapid recruitment of TCL1, AKT, and tyrosine kinases to membrane-associated activation complexes.[45]

TCL1 protein expression as shown by immunohistochemistry is normally observed in early T-cell progenitors and in the lymphoid cells of B lineage (both progenitors and mature lymphocytes, especially mantle zone cells), but not in mature T lymphocytes.[61,62] In T-PLL, a distinct positivity is found (**Fig. 31-4**), but other postthymic T-cell lymphomas, including cutaneous T-cell lymphoproliferations, are negative.[17,63]

In most T-PLL cases, changes involving chromosome 14 are accompanied by other complex abnormalities. Unbalanced rearrangements of chromosome 8 have been reported frequently, mainly trisomy 8q; monosomy 8p, such as i(8)(q10); and t(8;8)(p12;q11) or translocations involving 8p and other chromosomal partners.[57,64] Genes commonly affected by breaks on chromosome 8

were *PLEKHA2, NBS1, NOV,* and *MYST3*.[60] Although rearrangement of *MYC* has not been described, overexpression of c-MYC protein has been shown.[65] Thus, additional copies of *MYC* may represent a secondary abnormality, providing a proliferative advantage.

Abnormalities of chromosome 11, including recurrent losses of the 11q21-q23 regions, have also been detected with fluorescence in situ hybridization (FISH) or loss-of-heterozygosity analysis. Biallelic inactivation (missense mutations) of the *ATM* gene located at 11q21-q23 was demonstrated in virtually all sporadic cases of T-PLL, suggesting *ATM* has a tumor-suppressor gene function.[66,67] Truncating mutations in the *ATM* gene are the main cause of ataxia telangiectasia, a rare familial recessive disorder involving progressive neurologic disease, immunodeficiency syndrome, and chromosomal instability. In patients with ataxia telangiectasia, small clones harboring cytogenetic alterations involving 14q11 (AT clonal proliferations) may be seen several years before the onset of T-PLL.[13] Knockout mice with a complete ataxia telangiectasia–like phenotype consistently produced immature (CD3-negative, CD4-positive, CD8-positive) T-cell thymic lymphomas that arise coincidentally with V(D)J recombination.[68] Development of these malignancies in knockout mice can be prevented by bone marrow transplantation, which replaces the ATM-deficient hematopoiesis.[69]

Other reported abnormalities detected by loss-of-heterozygosity analysis, FISH, or conventional cytogenetics include deletions of 12p13; deletions or translocations involving 5p, 6q, 13q14.3, or 17p; and monosomy 22.[6,57,60,70,71]

Most of the abnormalities were confirmed by comparative genomic hybridization analysis that showed an abnormal profile in virtually all cases, with several recurrent abnormalities present in each T-PLL case.[72,73] The number of chromosomal alterations was not related to morphologic characteristics or the clinical behavior of the disease. Combined SNP-based genomic mapping and global gene-expression profiling showed that several of the upregulated genes in T-PLL are involved in the regulation of transcription, nucleosome assembly, translation, and cell-cycle control (e.g., Nijmegen breakage syndrome 1 *[NBS1], TCF7L, CCNB2, CCNB1, CCNG2, PFAS, PAICS, HIST1H2AE, HIST1H2B, HIST1H4G, ELF4EBP1, ELL3*). In contrast, various proapoptotic genes, such as *FAS, CASP1, CASP4, CASP8, STK17A,* and *TRAIL,* were downmodulated.[74]

Whole-genome sequencing and whole-exome sequencing studies showed largely mutually exclusive mutations of *IL2RG, JAK1, JAK3,* or *STAT5B* in 76% of studied T-PLL cases.[75,76] A large meta-analysis of primary data from 275 T-PLL cases from 10 published studies that evaluated genomic lesions involving elements of JAK/STAT signaling identified genomic aberrations potentially leading to constitutive JAK/STAT signaling in approximately 90% of cases.[77]

Postulated Cell of Origin

The cell of origin of T-PLL is unclear, but immunophenotypic and TCR gene rearrangement studies suggest a T cell with a postthymic phenotype. In >95% of T-PLL cases, aberrant constitutive expression of the protooncogenes *TCL1A* or *MTCP1* by inversions or translocations are observed that juxtapose the *TCL1A* (at 14q32.1) or *MTCP1* (at Xq28) loci to the 14q11.2 locus and by that under control

of highly active TRA gene enhancer elements. Lack of physiologic downregulation of TCL1A or MTCP1 is considered the initial event of T-PLL's leukemogenesis. The proposed model of clonal evolution of T-PLL cells[7,8] involves translocations or inversions of chromosome 14q at the double-positive thymocyte stage, resulting in constitutive expression of the protooncogenes *TCL1A* or *MTCP1*. These hits impair the genomic stability of the affected T cell by reduced DNA repair capacities of DNA double-stranded breaks or other (oxidative) insults. Deletions and mutations involving *ATM* lead to a functionally hypomorphic apical regulator of repair, cell fate, and cell-cycle control of the T-PLL precursor. This preleukemic cell becomes unable to execute such safeguarding mechanisms upon genotoxic stress. Subsequently, TCL1A overexpression lowers TCR signaling thresholds, enabling the cell to sustain on low-level input, either by major histocompatibility complex (MHC)-dependent (auto) antigen-presenting cells, by self-MHC drive only, or by autonomous TCR activation. A central distal node is the JAK/STAT transcriptional machinery. Besides major growth pathways such as the TCR and cytokine-mediated cascades feeding into it, there also is a high prevalence of hyperactivating mutations that target *JAK1, JAK3,* or *STAT5B* and a high incidence of losses of JAK/STAT negative regulators.

Clinical Course

The clinical course of T-PLL is usually aggressive, with progressive disease and median survival of 7 to 8 months from diagnosis. There is a poor response to treatment or early relapse after a short remission.[11,15] About one-third of patients in a large French study

and several separately described patients had an initially indolent clinical course, lower and stable leukocytosis, no anemia or thrombocytopenia, and no splenomegaly or skin changes.[16,79,80] The morphologic and cytogenetic characteristics of this group were similar to those of patients with aggressive disease. The stable phase had a median duration of 33 months (range, 6 to 103 months), but in seven patients, it was longer than 5 years, and one patient survived for 15 years.[16] At progression, an aggressive clinical course was observed.

Treatment

Only rare patients with T-PLL respond to single-agent therapy with alkylating drugs. Approximately 30% of patients achieve short-term remissions with combination chemotherapy, such as CHOP (cyclophosphamide, hydroxydaunomycin, Oncovin [vincristine], prednisone).[15,18,19] Pentostatin treatment produced better results, with 40% overall response and 12% complete remission for a median duration of 6 months.[81] Patients presenting with stable asymptomatic lymphocytosis may be closely monitored until progression. So far, the best treatment response has been achieved in patients treated with humanized anti-CD52 monoclonal antibody (alemtuzumab [Campath-1H]).[11,82-85] Response to alemtuzumab seems to be the most important predictor of outcome.[11] In slow responders, pentostatin may be added to alemtuzumab therapy.[11] Because long-term follow-up showed that all alemtuzumab-treated patients eventually relapsed,[84] all eligible patients who respond to therapy should be considered for consolidation with allo-HSCT.[11,86] Autologous HSCT may also be of benefit but will not result in cure.[87]

Induction of apoptosis via reactivation of p53 (e.g., by inhibitors of HDAC or MDM2) and targeting of its downstream pathways (i.e., BCL2 family antagonists, CDK inhibitors) are promising new approaches.[88] Novel strategies also focus on inhibition of the JAK/STAT pathway with the first clinical data.[89] Implementations of immune-checkpoint blockades or CAR-T cell therapy are at the stage of preclinical assessments of activity and feasibility.[90]

Differential Diagnosis

With modern immunophenotyping by flow cytometry or immunostaining of paraffin tissue sections, the differentiation between B-PLL and T-PLL is rather straightforward owing to the presence of the monoclonal B cell (CD19 and CD20 positivity and light-chain restriction by flow cytometry or PAX5, CD20, and CD79a expression by immunohistochemistry) or T-cell phenotype, respectively. Similarly, T-cell acute lymphocytic leukemia (T-ALL) can be easily distinguished from T-PLL by the expression of TdT or CD1a in T-ALL. The differential diagnosis between T-PLL and other mature T-cell leukemia/lymphomas (e.g., adult T-cell leukemia/lymphoma, mycosis fungoides–Sézary syndrome, large granular lymphocytic leukemia, and hepatosplenic T-cell lymphoma) may be more of a challenge because of highly overlapping morphology and partly overlapping immunophenotypes (especially if a limited panel of markers is applied). The possibility of leukemic presentation of peripheral T-cell lymphoma should also be considered, as cases with blood cytology and immunophenotype findings characteristic of T-PLL but lymph node morphology consistent with large cell T-cell lymphoma have been described.[33]

The main differentiating features helpful in obtaining the correct diagnosis are summarized in **Table 31-1**.

Table 31-1

ATLL, Adult T-cell leukemia/lymphoma; *HSTCL,* hepatosplenic T-cell lymphoma; *HTLV-1,* human T-lymphotropic virus type 1; *LGLL,* large granular lymphocytic leukemia; *MF-SS,* mycosis fungoides–Sézary syndrome; *NK,* natural killer; *PTCL,* peripheral T-cell lymphoma; *TCR,* T-cell receptor; *TIA-1,* T-cell-restricted intracellular antigen; *T-PLL,*T-cell prolymphocytic leukemia.

* May occur late in disease course.

Pearls and Pitfalls

- Peripheral blood lymphocytosis greater than 100×10^9/L is common, and cases with extreme hyperlymphocytosis occur.
- Different cytomorphologic characteristics of neoplastic cells are described, but in each case, the cells usually show a fairly high degree of cytologic monomorphism.
- Specific genetic abnormalities and immunologic phenotypes do not correlate with morphologic variants.
- Overexpression of TCL1 protein (or its functional homologues) and certain clinical features (e.g., markedly elevated lymphocyte count) provide a higher degree of diagnostic specificity than cytologic characteristics of neoplastic cells, histomorphologic patterns of bone marrow involvement, or

immunophenotype. However, TCL1 expression is not mandatory for diagnosis.

- Even in cases with CD8-positive expression, the neoplastic cells do not express cytotoxic granule molecules.
- The characteristic pattern of splenic infiltration involves both red pulp and white pulp, with effacement of normal splenic architecture.

DIFFERENTIAL DIAGNOSIS

Definition

Adult T-cell leukemia/lymphoma (ATLL) is a mature T-cell neoplasm pathogenetically linked to human T-lymphotropic virus 1 (HTLV-1; also called *human T-cell leukemia virus*). This is the first retrovirus proved to cause a human neoplasm.[1-3] The disease is derived from mature CD4-positive T cells, and most patients have widely disseminated disease that can be leukemic or lymphomatous in distribution.[4] A characteristic feature is the marked nuclear pleomorphism associated with the neoplastic cells, which have been termed *flower cells*.[5,6] Because of its unique clinical and pathologic features, adult T-cell leukemia was recognized as a disease entity before HTLV-1 was identified as a causal factor.[7]

Synonyms and Related Terms

The term of this entity has been maintained from the International Consensus Classification (ICC) and the 5th edition of the World Health Organization (WHO) Classification of Haematolymphoid Tumours.

Epidemiology

ATLL is endemic in several regions of the world, in particular southwestern Japan, the Caribbean basin, parts of central Africa, and Iran.[8-11] The distribution of the disease is closely linked to the prevalence of HTLV-1 in the population: serologic surveillance has suggested an origin in Africa spread to Austro-Melanesia and the Asian continent, and later North America and South America[12] (**Box 32-1**; **Fig. 32-1**). The disease has a long latency, and affected individuals are usually exposed to the virus very early in life. Cord blood lymphocytes are more susceptible to transformation than

more fully differentiated and mature lymphocytes.[13] The three major routes of infection are mother-to-infant transmission, mainly in breast milk; sexual transmission; and transmission through blood and blood products. The virus is not transmitted in fresh frozen plasma, and transmission requires the presence of living HTLV-1–infected cells.[14] In Japan, where the disease was first described, seroprevalence in the adult population ranges from 0.2% in some areas to 13% in areas of high endemicity.[10] The cumulative risk for carriers during the adult life span is 2.5%, with an ongoing increased risk until 70 years of age. Most cases present in adulthood (median age, 55 years), with a male-to-female ratio of 1.5:1.

In the Western Hemisphere, most patients come from the Caribbean basin, and the disease is more prevalent among Blacks than Whites.[8] Other areas of prevalence include Central and South America, in particular Brazil and Ecuador. Differences in geographic or ethnic origin correlate with different patterns of disease, with most cases in the Western world presenting as lymphoma rather than leukemia.[15] It is not entirely clear how genetic factors influence the development of ATLL in infected carriers. At least two studies suggest that human leukocyte antigen (HLA) haplotypes correlate with progression to ATLL in infected individuals.[12,16]

The virus has been linked to other disease entities besides ATLL. Young infected children may be immunodeficient and present with superficial cutaneous infections, a pattern termed *infective dermatitis*.[17] HTLV-1–associated myelopathy (HAM), also known as *tropical spastic paralysis* (TSP), is a systemic disease associated with neurologic symptoms and demyelinization.[18] It is thought to be an immune-mediated inflammatory disease with some parallels to

multiple sclerosis.[19] Patients with HAM/TSP often acquire the virus later in life through transfusion and rarely develop ATLL. In addition to neurologic symptoms of weakness and muscle spasms, patients with HAM/TSP may manifest uveitis, arthritis, polymyositis, keratoconjunctivitis sicca resembling Sjögren syndrome, and pulmonary inflammation.

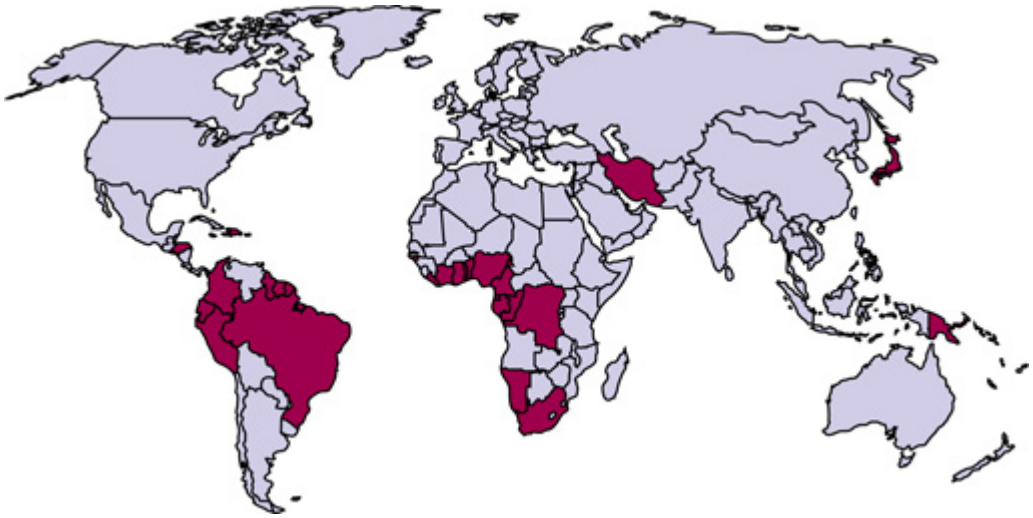

FIGURE 32-1 Map of the world showing the geographic distribution of HTLV-1 prevalence. Areas in *red* have greater than 2% prevalence in the population.

Box 32-1 Major Diagnostic Features of Adult T-Cell Leukemia/Lymphoma

ATLL, Adult T-cell leukemia/lymphoma; *EBV,* Epstein-Barr virus; *HTLV-1,* human T-lymphotropic virus 1.

Epidemiology

- ATLL is strongly associated with geographic prevalence of HTLV-1.
- ATLL risk is closely linked to HTLV-1 infection in the perinatal period or infancy.

Clinical Features

- Acute and lymphomatous types of ATLL are highly aggressive.
- Chronic and smoldering types of ATLL have a more protracted clinical course.

Morphology

- Appearance of neoplastic cells demonstrates a wide spectrum, including polylobated cells with hyperchromatic nuclei and transformed or blastic cells with round-to-oval nuclei.

Immunophenotype

- $CD3^+$, $CD4^+$, $CD25^+$, $CD7^-$, αβ T cells, $FOXP3^{+/-}$
- EBV^+ B cells may be present in the background and may mimic Hodgkin cells in incipient ATLL.

Molecular and Genetic Features

- Clonal T-cell receptor gene rearrangement
- Clonal integration of HTLV-1
- *Tax* gene plays a major role in viral oncogenesis.

Clinical Features

Several clinical variants are recognized: acute, lymphomatous, chronic, and smoldering (**Table 32-1**).[6] Because nearly all patients have advanced disease (stage IV) at presentation, Ann Arbor staging is not prognostically useful. The most common acute variant is characterized by a leukemic phase, often with a markedly elevated white blood cell count, rash, and generalized lymphadenopathy. Hypercalcemia, with or without lytic bone lesions, is common (**Fig. 32-2**). Patients with acute ATLL have systemic disease with hepatosplenomegaly, constitutional symptoms, elevated lactate dehydrogenase, and marked elevation of soluble interleukin (IL)-2 receptors, which is an independent prognostic factor.[20] Infiltration of any organ system may be evident, including the central nervous system.[21] Leukocytosis and eosinophilia are common. The bone marrow may be hypercellular, with myeloid hyperplasia. Despite stage IV disease and peripheral blood involvement, bone marrow involvement may be absent. Many patients have an associated T-cell immunodeficiency and frequent opportunistic infections, most notably by *Pneumocystis jiroveci* and *Strongyloides stercoralis* (**Fig. 32-3**).[22] An increased risk for viral infection is also present, including cytomegalovirus and herpes zoster infections.

The lymphomatous variant is characterized by prominent lymphadenopathy without peripheral blood involvement. Most patients have advanced disease, similar to the acute form. However, hypercalcemia is present less often. The lymphomatous variant is seen more often in the Western Hemisphere. Patients presenting with lymphadenopathy may have peripheral blood involvement later

in the course of the disease.[23] The lymphomatous and acute forms have comparable survival, usually less than 1 year.

The chronic variant is associated with skin lesions, most commonly an exfoliative rash (**Fig. 32-4**). Although there may be an absolute lymphocytosis, atypical lymphocytes are not numerous in the blood. Flower cells, if present, are associated with a more aggressive clinical course.[24,25] Hypercalcemia is absent. Patients may have hepatosplenomegaly, but the course is generally indolent, with a median survival of approximately 2 years.

In the smoldering variant, the white blood cell count is normal, with less than 5% circulating neoplastic cells. Patients frequently have skin or pulmonary lesions, but hypercalcemia is not present. Lymphadenopathy should be absent. Patients may progress from chronic or smoldering disease to an acute crisis.

The skin is the most common site of involvement outside of the peripheral blood, with more than 50% of patients having evidence of cutaneous disease.[26-28] The skin lesions are clinically diverse and range from an exfoliative rash to papules and nodules, with the larger nodules showing ulceration (**Fig. 32-5**).[29] More extensive cutaneous disease, with papules and nodules, appears to correlate with a more aggressive course. The number of circulating neoplastic cells does not correlate with the degree of bone marrow involvement, suggesting that circulating cells are recruited from other organs, such as the skin. Other sites of clinically relevant disease include the gastrointestinal tract, lungs, liver, and central nervous system, all of which may lead to clinical symptoms and morbidity.[21,30] Cardiac involvement may be seen as well, usually as a terminal event.[31]

Morphology

The cytologic spectrum of ATLL is extremely diverse. Nevertheless, certain cytologic features are highly characteristic and may suggest the diagnosis, even if studies for HTLV-1 are not performed.[32] These features are best appreciated in the peripheral blood (**Fig. 32-6**). Most patients are leukemic at some point in the clinical course, although peripheral blood involvement may not be evident at presentation.

The neoplastic cells in the peripheral blood are markedly polylobated and have been termed *flower cells* based on the petal-like appearance of the nuclear lobes.[5,6,23] The chromatin is condensed and usually hyperchromatic, although the flower cells usually do not manifest prominent nucleoli. The cytoplasm is basophilic, and cytoplasmic vacuoles may be seen. The basophilic cytoplasm and hyperchromasia are useful features in distinguishing ATLL from Sézary syndrome. In addition, the nuclear irregularities in Sézary cells are much subtler, imparting the typical cerebriform appearance without separation into nuclear lobes.

FIGURE 32-2 Skull radiograph shows multiple osteolytic bone lesions in a patient with acute adult T-cell leukemia/lymphoma.

Table 32-1

LDH, Lactate dehydrogenase; *PCR,* polymerase chain reaction.

These cytologic features are most evident in the acute type of ATLL. In the chronic and smoldering forms of the disease, atypical cells are relatively sparse in the peripheral blood, and cytologic atypia is less evident.[33,34]

Lymph node involvement is present in most patients. Lymph nodes typically show diffuse architectural effacement. In keeping with a leukemic pattern of involvement, in some instances the sinuses may be preserved or may contain neoplastic cells similar to those in the blood (**Fig. 32-7**). Preservation of the sinuses is more common in patients with leukemic disease. The cytologic composition of the neoplastic infiltrate is very diverse. Small pleomorphic lymphoid cells equivalent to the flower cells of the peripheral blood may predominate or may be admixed with larger transformed cells (**Fig. 32-8**). The transformed cells have vesicular nuclei and usually multiple eosinophilic or basophilic nucleoli. These cells may be relatively uniform in size, with round-to-oval nuclear contours, resembling diffuse large B-cell lymphoma (**Fig. 32-9**). Alternatively, the transformed cells may have more pleomorphic nuclear features. Giant cells with convoluted or cerebriform nuclear contours may be present. Although it is important for the pathologist to be aware of the diverse cytology that can be encountered in ATLL, the size or shape of the neoplastic cells generally does not affect the clinical course.[23] Some patients with incipient ATLL, such as the smoldering type, may exhibit a Hodgkin lymphoma–like histology in the lymph nodes that is associated with less aggressive disease (**Fig. 32-10**).[35-38]

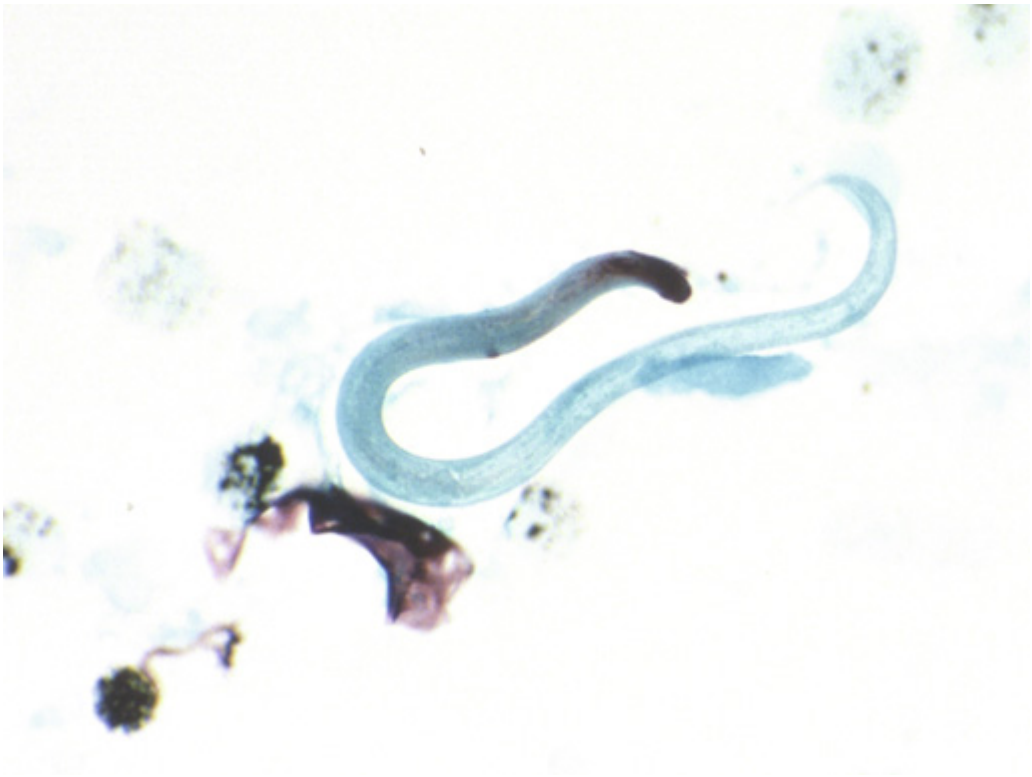

FIGURE 32-3 Bronchoalveolar lavage specimen shows a larval form in a patient with adult T-cell leukemia/lymphoma and disseminated strongyloidiasis.

Involved lymph nodes show expanded paracortical areas with diffuse infiltrates of small to medium-sized lymphocytes with mild nuclear irregularities, indistinct nucleoli, and scant cytoplasm. There are interspersed Reed-Sternberg–like cells and giant cells with lobulated or convoluted nuclei. These cells are Epstein-Barr virus (EBV)-positive B lymphocytes that express CD30 and CD15. This variant of incipient disease usually progresses to overt disease within months. In its early stages, neoplastic HTLV-1–positive cells may be few in these lesions, and in fact, the T-cell proliferation may not be clonal. Thus in some respects, this incipient form of ATLL may be

preneoplastic. Alternatively, the number of HTLV-1–infected T cells may be beneath the threshold for detection by polymerase chain reaction (PCR) methods for identifying T-cell receptor gene rearrangement. The expansion of EBV-positive B cells is thought to be secondary to the underlying immunodeficiency in patients with ATLL. Similar Reed-Sternberg–like cells have been described in other forms of peripheral T-cell lymphoma, most commonly angioimmunoblastic T-cell lymphoma.[39] This must be distinguished from HTLV-1–infected cells with Hodgkin and Reed-Sternberg morphology that are positive for CD30, CD15, MUM1, CD25, and HTLV-1 and negative for B-cell makers, including PAX5 and EBV.[40]

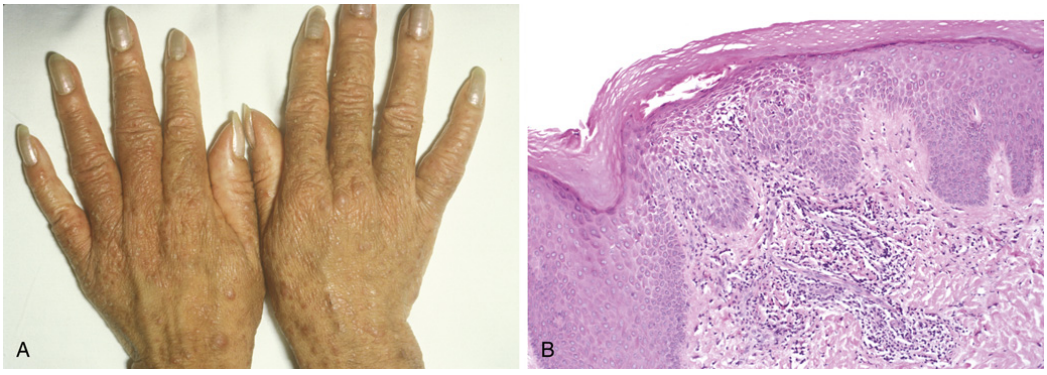

FIGURE 32-4 Chronic adult T-cell leukemia/lymphoma.A, Skin shows evidence of scaling and hyperkeratosis. **B,** Skin biopsy from the same patient shows a dermal lymphocytic infiltrate composed of small lymphoid cells without significant atypia.

FIGURE 32-5 Diverse cutaneous manifestations of adult T-cell leukemia/lymphoma range from exfoliative rash **(A)** to papules **(B)** to larger nodules with ulceration **(C)**.

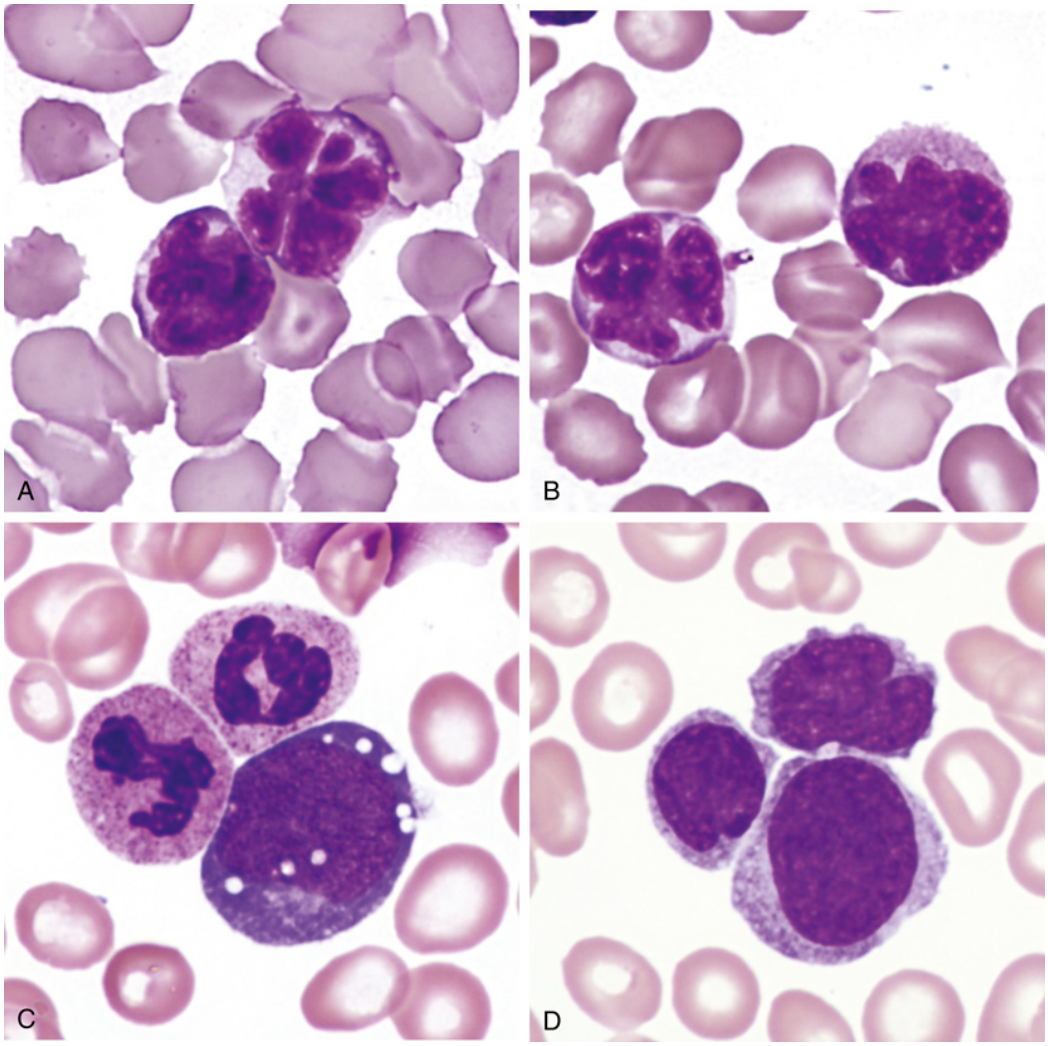

FIGURE 32-6 Peripheral blood findings in adult T-cell leukemia/lymphoma. Flower cells with markedly polylobated nuclei (**A** and **B**) are most common, but one can also see blast-like cells **(C)** and cells with rounder nuclear contours **(D)**.

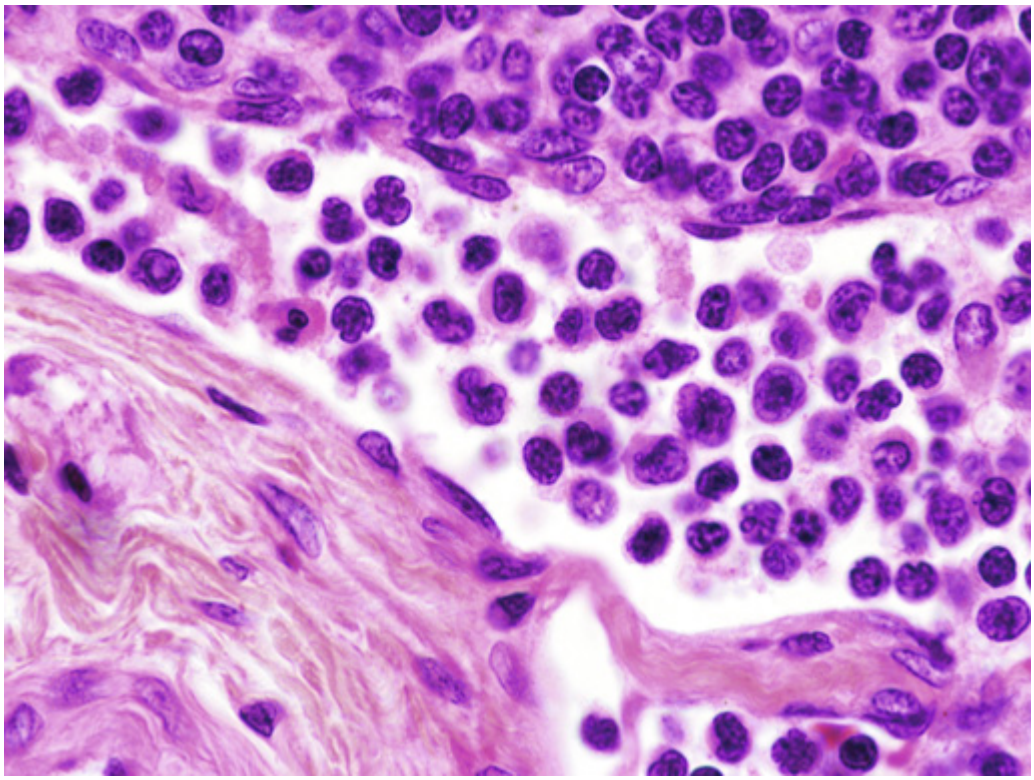

FIGURE 32-7 Lymph node in a patient with adult T-cell leukemia/lymphoma. In the leukemic phase, dilated sinuses may contain atypical cells.

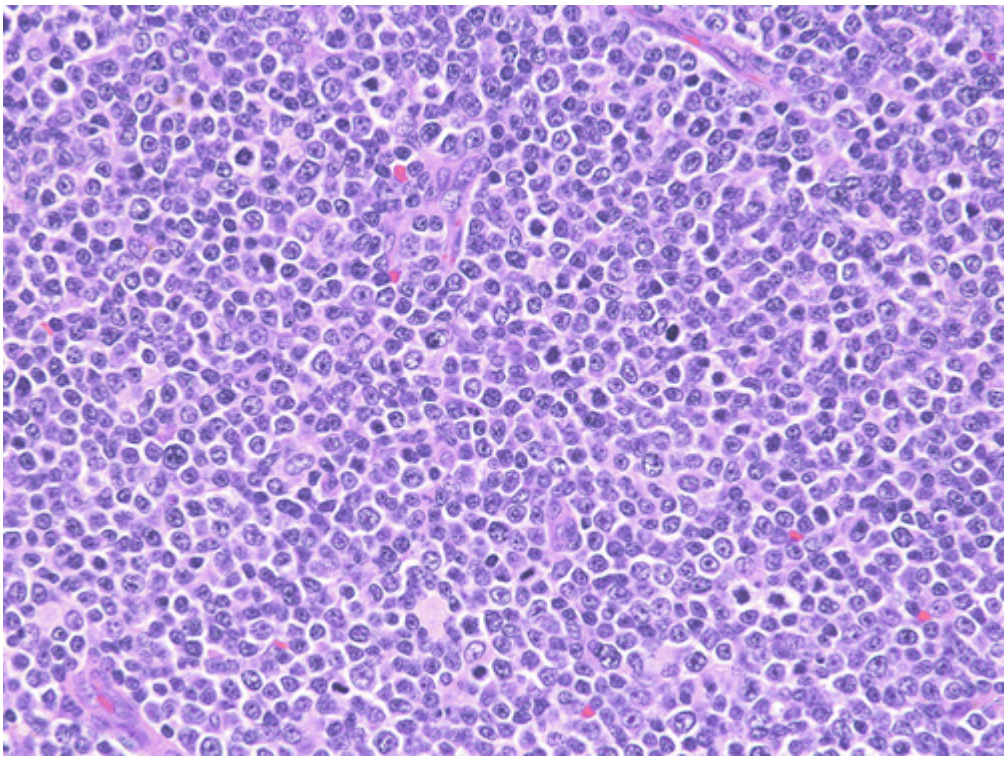

FIGURE 32-8 Lymph node in a patient with adult T-cell leukemia/lymphoma. Small pleomorphic lymphoid cells may be admixed with larger blast-like cells with vesicular nuclei and prominent nucleoli.

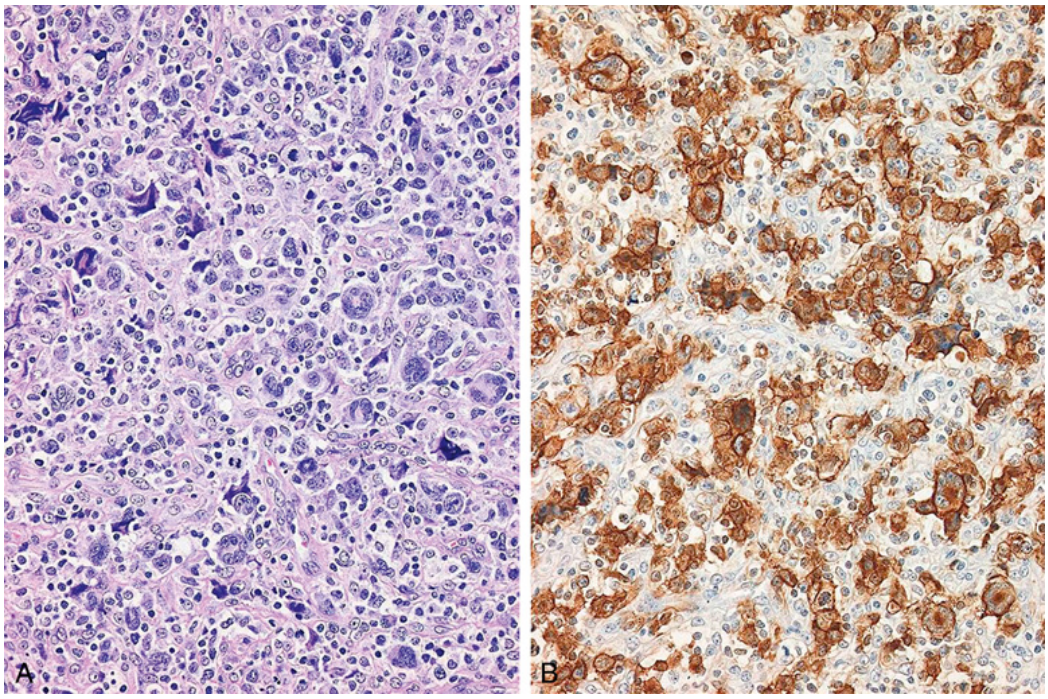

FIGURE 32-9 Lymph nodes in patients with adult T-cell leukemia/lymphoma.A, In this case, cells with blastic features predominate. The process may mimic a diffuse large B-cell lymphoma if immunohistochemical studies are not performed. **B,** Giant cells with pleomorphic nuclei and CD30 positivity may be present as well (**B:** immunoperoxidase with hematoxylin counterstain).

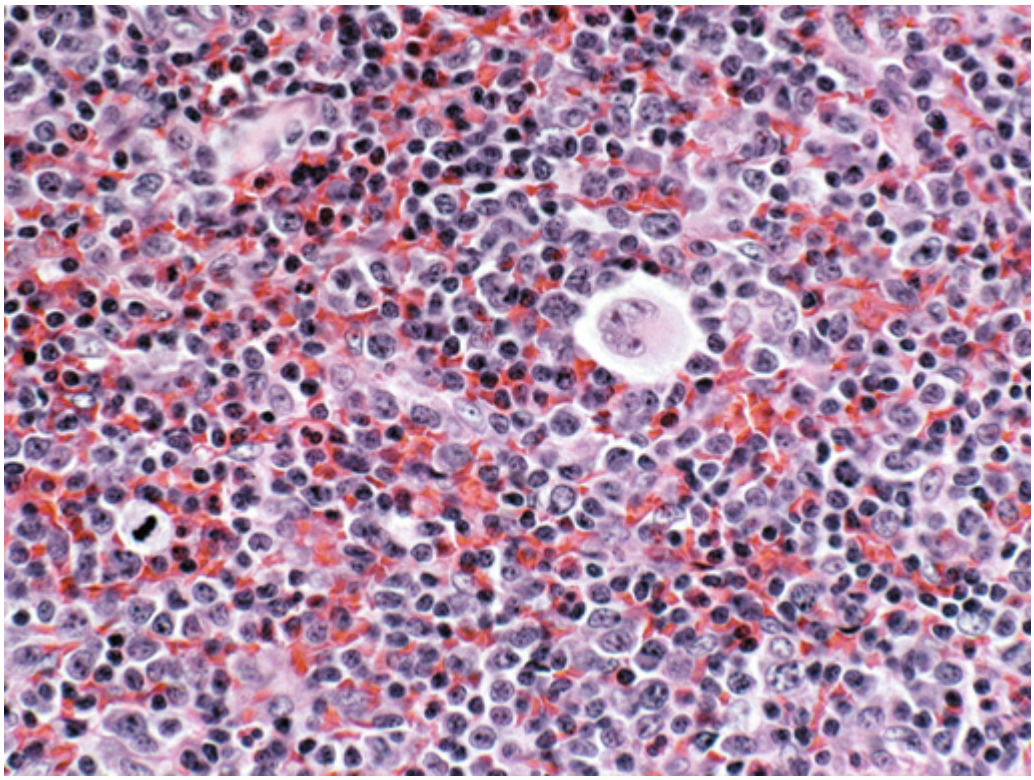

FIGURE 32-10 Lymph node in a patient with incipient adult T-cell leukemia/lymphoma. Cells resembling Hodgkin and Reed-Sternberg cells may be present, mimicking classic Hodgkin lymphoma. The Hodgkin-like cells are Epstein-Barr virus–positive transformed B cells, and the background contains HTLV-1 T cells.

Skin involvement is seen in more than 50% of patients with the disease. The dermis usually contains a superficial atypical lymphoid infiltrate, often with epidermotropism (**Fig. 32-11**).[26] Pautrier-like abscesses are common.[23] However, in contrast to Sézary syndrome or mycosis fungoides, the neoplastic infiltrate is usually monomorphic and relatively confluent, without numerous histiocytes

or eosinophils. The smaller neoplastic cells usually predominate in the skin. In the smoldering and chronic types, cytologic atypia may be minimal. Hyperparakeratosis is variably present in the overlying epidermis. The skin lesions are clinically and histologically diverse and may mimic inflammatory disorders.[41]

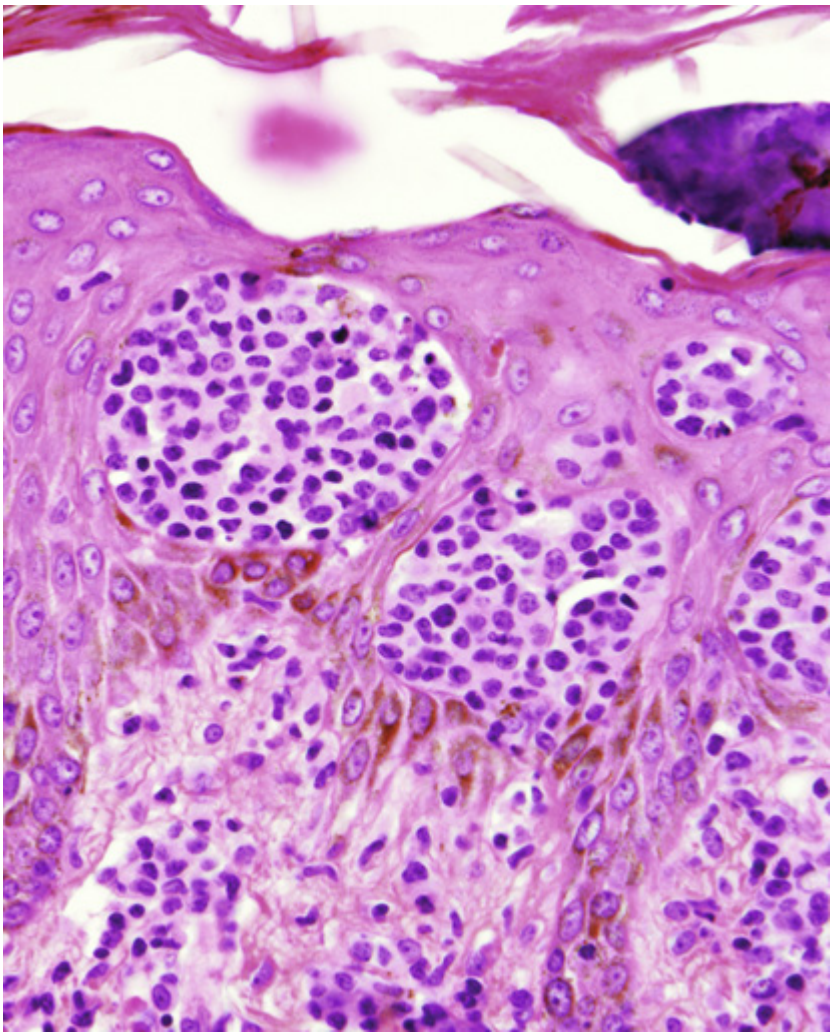

FIGURE 32-11 Skin biopsy specimen in adult T-cell leukemia/lymphoma. There is marked epidermotropism, with infiltration of the overlying epidermis.

Bone marrow involvement is typically not prominent. The marrow may contain patchy atypical lymphoid infiltrates. However, the degree of bone marrow infiltration is less than expected, given the marked lymphocytosis that may be present. Bone resorption and osteoclastic activity is often seen in patients with hypercalcemia (**Fig. 32-12**).[42] Bone trabeculae may show evidence of remodeling, and in some patients, lytic bone lesions are present, even in the absence of tumoral bone infiltration (**Fig. 32-13**).[21]

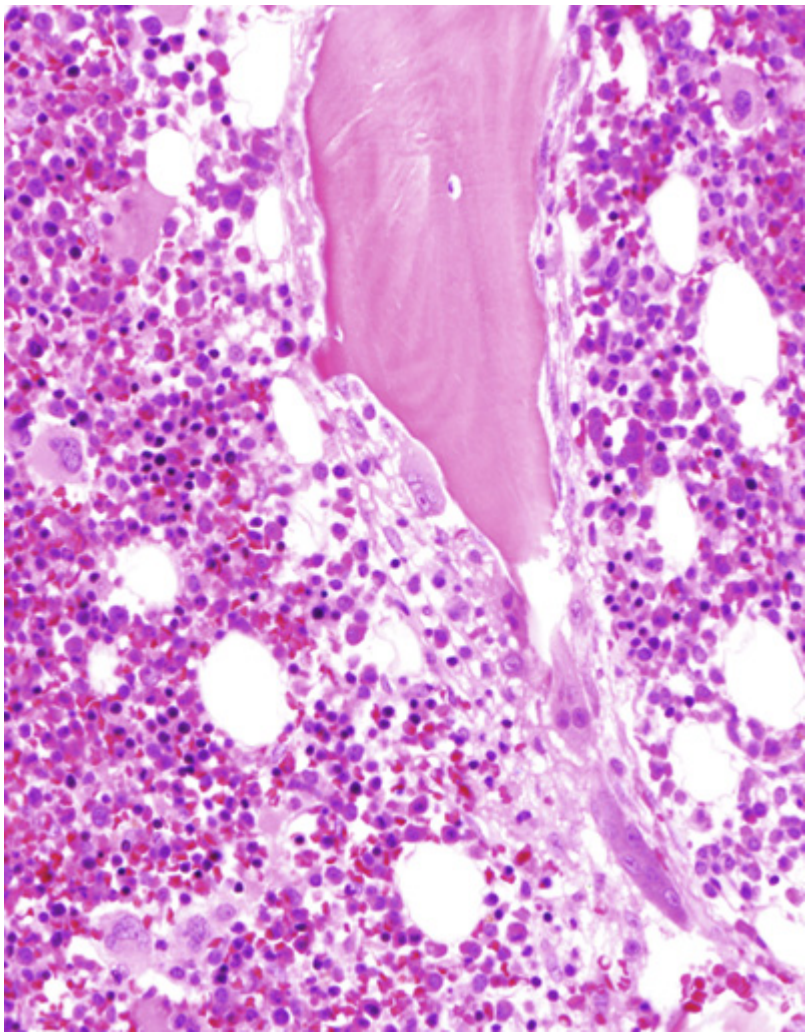

FIGURE 32-12 Bone marrow core biopsy in adult T-cell leukemia/lymphoma. The bone marrow space shows myeloid hyperplasia without identifiable tumor cells. However, the bone trabeculae show evidence of remodeling and increased osteoclasts.

Other frequent sites of involvement include the lung and cerebrospinal fluid. Correlating with a leukemic phase, the pulmonary infiltrates are generally patchy and interstitial, with no formation of tumor nodules. Cardiac involvement has been reported

rarely and is always associated with concomitant pulmonary involvement (**Fig. 32-14**).[31]

Involvement of the central nervous system usually manifests as meningeal infiltration without nodular parenchymal lesions. Neoplastic cells may be detected in cytologic preparations of cerebrospinal fluid. However, rare cases with parenchymal tumor masses have been reported.[43] Central nervous system involvement is nearly always associated with widespread systemic disease, but rare cases with isolated central nervous system involvement have been reported.[25]

Although there is no formal cytologic grading system for ATLL, the neoplastic cells in the chronic and smoldering variants of the disease usually show minimal cytologic atypia, perhaps in keeping with the more indolent clinical course.

Immunophenotype

The neoplastic cells, regardless of cytologic subtype, are CD4-positive αβ T cells that strongly express the α chain of the IL-2 receptor (IL-2R) or CD25 (**Fig. 32-15**).[44] High levels of soluble IL-2R can also be found in the serum and correlate with disease activity.[45] CD7 is nearly always absent, but CD3 and other mature T-cell antigens (CD2, CD5) are usually expressed. CD52 is usually positive, a finding of clinical relevance for the use of anti-CD52 humanized antibody (alemtuzumab [Campath]) for treatment purposes. CD30 can be expressed in the larger blastic cells, and it is also a target of antibody therapy (brentuximab vedotin). CC chemokine receptor 4 (CCR4) is usually expressed and is closely associated with skin involvement and poor outcome.[46] Anti-CCR4 antibody (mogamulizumab) has

been effective therapeutically.[47] Because many peripheral T-cell lymphomas have a CD3-positive, CD4-positive, CD7-negative immunophenotype, the most specific feature of ATLL is strong CD25 positivity. With enhanced antigen-retrieval techniques, CD25 expression can be detected in formalin-fixed, paraffin-embedded tissue sections.[48] Because of its strong expression, CD25 has become a target of immunotherapy for ATLL.[44] Studies suggest that ATLL cells may be the equivalent of regulatory T (Treg) cells.[49,50] In one study, 68% of the cases tested were positive for the Treg transcription factor FOXP3 in at least some of the neoplastic cells, although usually only a small minority. No other T-cell lymphoma subtype expresses FOXP3 in conjunction with CD25 and CD4. This finding helps explain the immunodeficiency associated with ATLL. FOXP3-positive cases appear to be a lower grade, manifesting fewer cytogenetic abnormalities.[51] TSLC1/CADM1 has been proved to be a marker of neoplastic cells in ATLL that plays a role in tumor growth and organ infiltration of ATLL cells.[52-54]

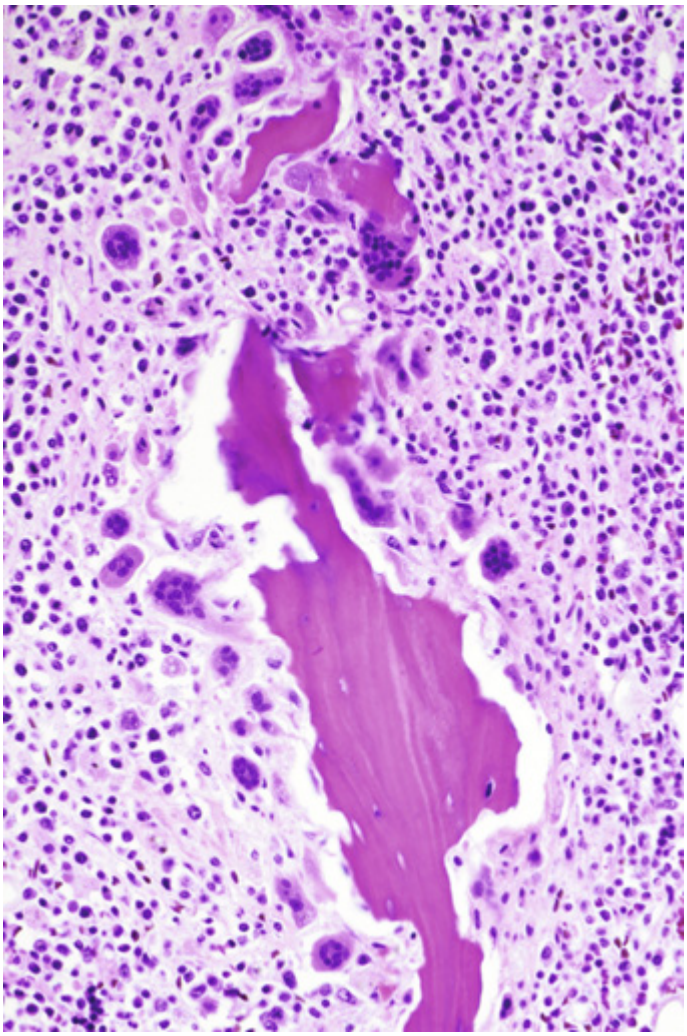

FIGURE 32-13 Lytic bone lesion in adult T-cell leukemia/lymphoma. Numerous osteoclasts surround bone trabeculae.

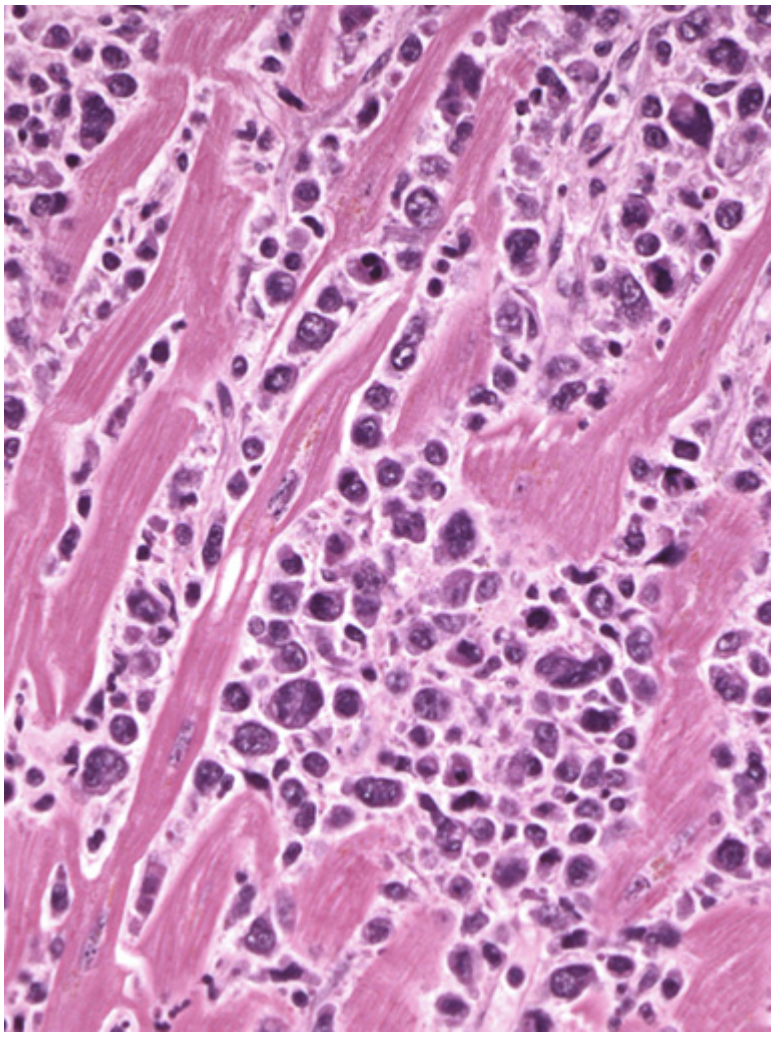

FIGURE 32-14 Cardiac involvement by adult T-cell leukemia/lymphoma.

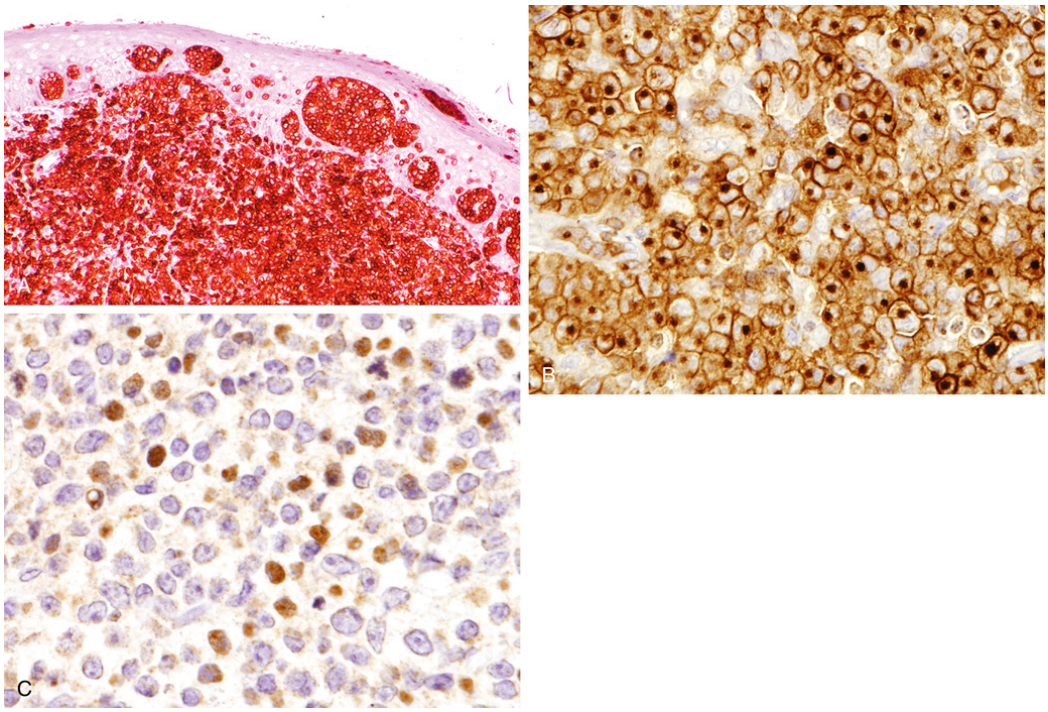

FIGURE 32-15 Immunohistochemistry of adult T-cell leukemia/lymphoma.A, Skin biopsy shows positive staining for CD3 in epidermal and dermal lymphoid cells. **B,** Tumor cells show strong membrane and Golgi staining for CD25. **C**, A subpopulation of tumor cells is positive for FOXP3, with the larger atypical cells being negative. (**A** to **C,** immunoperoxidase with hematoxylin counterstain.)

Genetics, Molecular Findings, and Role of HTLV-1

ATLL has clonal rearrangement of the T-cell receptor genes. In patients with acute or lymphomatous ATLL, there is evidence of a single dominant clone in all sites involved by the disease. HTLV-1

carriers do not show a dominant T-cell clone but may have oligoclonal T-cell expansion. The high-density expression of IL-2R renders these cells responsive to growth in response to cytokines both in vitro and in vivo.[55] Similarly, in the early phases of smoldering or chronic ATLL, more than one T-cell clone may be present, with emergence of a dominant clone at the time of progression.[56]

The HTLV-1 proviral DNA is clonally integrated into neoplastic T cells.[35] Patients with incipient ATLL or those with early-stage disease may contain T-cell clones with defective or partial viral integration.[57] Southern blotting techniques are useful to follow the clone, as the unique site of integration produces a distinctive band.[58] PCR techniques for HTLV-1 sequences can be used to quantify the viral load in the peripheral blood.[59,60] Patients with HAM/TSP do not have circulating T cells with clonal integration of the HTLV-1 virus. However, in keeping with the aberrant immune response to HTLV-1 involved in HAM/TSP, clonal and oligoclonal T-cell populations directed against the virus may be identified.[61]

HTLV-1 is the first human retrovirus shown to cause malignant transformation.[1] It contains the structural genes *gag, pol,* and *env* and a pX region at the 3′ end that encodes the regulatory proteins Tax and Rex, among others. The viral gene *Tax* plays a pivotal role in HTLV-1–initiated leukemogenesis. The Tax protein is a transcriptional activator of the viral long-terminal repeat. Tax can act by transactivation to deregulate a variety of cellular genes, leading to activation of signal transduction,[62] deregulation of the cell cycle,[3] and induction of genetic instability, resulting in multiple cytogenetic

abnormalities.[63,64] Tax itself is oncogenic and can transform human T cells and rodent fibroblasts.[62]

Tax acts via several signal transduction pathways, including nuclear factor-κB (NF-κB), the CREB/ATF family (leucine zipper protein), serum response factor, and AP-1 families.[65] Tax can bind directly to several members of the NF-κB family of proteins.[66] Tax also binds to proteins that inhibit NF-κB, providing an alternative mechanism for NF-κB activation.

In addition, Tax can inactivate p53. Although many cases of ATLL show p53 mutation or deletion,[67] p53 is inactivated directly by Tax.[68] This promotes destabilization of the genome and the development of other genetic abnormalities. Tax also inhibits the cell-cycle regulator CDKN2A, promoting continuous cellular proliferation of HTLV-1–infected cells.[66]

Tax plays a role in the effects mediated by IL-2 and IL-15. The α chain of IL-2R was the first gene shown to be upregulated by Tax.[69] Tax upregulates the expression of both IL-2 and IL-15, a relative of IL-2, providing a mechanism for an autocrine loop in HTLV-1–infected cells.[70] IL-15 uses the β and γ chains of IL-2R for signaling. Tax also upregulates IL-15Rα in ATLL cells.[70] Other cellular genes may be activated by Tax, such as IL-6; this activity may be responsible for the hypercalcemia characteristic of ATLL by promoting the secretion of parathormone-like substances, leading to osteoclastic activation.[71,72] The hypercalcemia of ATLL can be replicated in Tax-transgenic mice.[73] Activation of NF-κB also appears to play a role in the production of osteoclast-activating factors.[72] Finally, ATLL cells express RANK ligand, which promotes the differentiation of hematopoietic precursors into osteoclasts.[14,74]

Although *Tax* seems to play a crucial role in ATLL leukemogenesis and is present in tumor cells in culture, the gene is not always expressed in primary ATLL cells. Instead, HTLV-1 bZIP factor (HBZ) is consistently detected in primary ATLL cells, and has been shown to affect multiple pathways involved in tumorigenesis.[75] HZB enhances TGF-β signaling, supports proliferation of ATLL cells through suppression of C/EBPα signaling,[76] suppresses apoptosis by attenuating the function of FoxO3a,[77] and dysregulates the Wnt pathways to support proliferation and migration of ATLL cells.[78] The relationship between Tax and HZB is interesting; HBZ is involved in suppression of Tax-mediated viral gene transcription, and HBZ specifically suppresses NF-κB–driven transcription.[79] Findings in HBZ/Tax double transgenic mice further support a role for HBZ in lymphomagenesis.[80]

Accumulation of aberrant DNA hypermethylation at the differentially methylated positions (DMPs) strongly correlates with ATLL development and progression. Region-specific aberrant DNA hypermethylation is mechanistically important for ATL leukemogenesis and an effective therapeutic target.[81,82] Another relevant epigenetic event in ATLL leukemogenesis is Polycomb-mediated aberrant gene expression. Aberrant overexpression of Ezh2, EED and Suz12, which are components of Polycomb repressive complex-2 (PRC2), induce methylation of histone H3 on lysine (K) 27, generating (H3-K27me3), followed by chromatin compaction and various target gene silencing in ATLL.[83-85] Overexpression of Ezh2 mediates down regulation of miR-31 expression, which induces activation of the NIK-dependent NF-κB pathway, contributing to leukemic transformation.[85,86]

ATLL cells show numerous complex structural cytogenetic abnormalities affecting every chromosome pair. There are no recurrent cytogenetic changes, however, that are useful in making the diagnosis.[87,88] Structural abnormalities occur most frequently in chromosome 6, and abnormalities in 6q appear to correlate with a more aggressive clinical course.[87] Translocations are identified in about 10% of cases involving the T-cell receptor-αδ gene locus on 14q11.[89] Comparative genomic hybridization studies have confirmed the diversity and frequency of genetic changes.[90] Different genetic changes were observed in the acute and lymphomatous subtypes, suggesting these two variants may proceed along different molecular pathways. The complexity of the cytogenetic abnormalities is likely mediated by Tax.[62,91,92] Tax impairs DNA repair mechanisms and represses the expression of DNA polymerase-β, an enzyme involved in base excision repair. Tax also represses nucleotide excision repair, which plays a critical role in repairing ultraviolet irradiation–induced damage.

Gene-expression profiling studies have identified overexpression of *BIRC5* (survivin).[93] The antiapoptotic function of *BIRC5* may also play a role in the resistance of ATLL cells to chemotherapy. Somatic alterations characterizing aggressive diseases predict worse prognosis in indolent ATLL, among which *PD-L1* amplifications are a strong genetic predictor for aggressive ATLL.[94] Structural variations (SVs) disrupting the 3′ region of the *PD-L1* gene stabilize and increase the expression of aberrant *PD-L1* transcripts in ATLL (27%).[95]

Thus, although HTLV-1 infection does not lead directly to malignant transformation of T cells, it promotes the development of

neoplastic transformation by a variety of mechanisms, including stimulation of T-cell growth, inhibition of T-cell death via apoptosis, deregulation of DNA repair mechanisms and promotion of chromosomal instability, and activation of signal-transduction pathways. The *Tax* gene plays a role in most of these actions. A large-scale genetic study delineated the entire portrait of genetic and epigenetic aberrations in ATLL and identified a large number of novel mutational targets.[67] However, the detailed mechanisms triggering the onset and progression of ATLL remains to be elucidated.[96]

Postulated Normal Counterpart

ATLL cells are αβ T cells that most closely resemble Treg cells. Treg cells play a major role in regulating the immune response, mainly by suppressing it. They require the transcription factor FOXP3 for functional development in the thymus gland[97] and have a CD3-positive, CD4-positive, CD25-positive phenotype. Although FOXP3 is not universally expressed in all cases of ATLL, it is expressed in some instances.[49,50]

Clinical Course

Acute and lymphomatous forms of ATLL have an aggressive clinical course, with a median survival of less than 1 year and a projected 4-year survival of only 5%.[98] Without treatment, most patients die within weeks to months; even with treatment, most remissions are short-lived.[6,21,99] Major prognostic indicators for acute ATLL include performance status, high lactate dehydrogenase, age (older than 40 years), more than three sites of disease, and

hypercalcemia.[100] Other factors that appear to affect prognosis include thrombocytopenia, eosinophilia, and bone marrow involvement. Some molecular alterations are associated with a more aggressive clinical course, including *CDKN2A* gene deletion[101] and *TP53* mutation.[102]

The clinical course is more protracted in patients with chronic or smoldering disease, but median survival is still less than 5 years for these patients. Prognostic factors of predictive value for chronic ATLL include high lactate dehydrogenase, low albumin, and high blood urea nitrogen levels.[100] Deletion of the *CDKN2A* gene in the chronic phase is also a negative prognostic factor, and gene deletion by comparative genomic hybridization correlates with a poor prognosis.[101,103] Genetic alterations also occur during progression from chronic-phase to acute-phase disease.[104]

Conventional chemotherapy regimens (doxorubicin based) have been largely ineffective, prompting the investigation of other agents, such as deoxycoformycin (pentostatin), with limited success.[105] More intensive high-dose chemotherapy and bone marrow transplantation have been used in a limited number of patients. Treatment-related mortality is very high, limiting the utility of this approach.[106] Because ATLL is caused by a retrovirus, there was speculation that drugs active against other retroviruses, such as human immunodeficiency virus (HIV), might show activity. Initial trials using zidovudine (AZT) and α-interferon suggested some efficacy,[107,108] but the initial good outcomes were not reproduced in subsequent studies.[109] However, this regimen may have a role in patients with smoldering or chronic disease.[100] In another study, a combination of arsenic and α-interferon was used, with the

suggestion that it might lead to the downregulation of *Tax*.[110] The efficacy of this approach has not been demonstrated in clinical trials. Promising results have been obtained in monoclonal antibody–based therapies directed against IL-2R, which is highly expressed in ATLL; the efficacy of humanized anti-CD25(Tac), either unconjugated or labeled with yttrium-90,[43,111] was highest in patients with chronic or smoldering disease. Other molecular targeted therapies, such as that against CCR4 and allogenic transplantation, are promising.[112,113] Anti-CCR4 antibody (mogamulizumab) and lenalidomide, have been approved for ATLL patients in Japan. The risk of severe, acute, and corticosteroid-refractory graft-versus-host disease was higher in patients who received mogamulizumab before allogeneic hematopoietic cell transplantation (allo-HCT). However, administration of mogamulizumab before allo-HCT tended to improve the survival of patients. Allo-HCT procedures for patients with aggressive ATLL have considerably progressed and have helped improve the prognosis of these patients.[114,115] Because ATLL has such a poor prognosis, clinical efforts to control the disease have been largely directed at preventing infection in susceptible populations.

Differential Diagnosis

The differential diagnosis of acute and lymphomatous ATLL differs somewhat from that of chronic or smoldering ATLL (**Table 32-2**). The clinical picture of acute ATLL with hypercalcemia and systemic disease usually prompts consideration of the diagnosis. The diagnosis of ATLL may be less obvious in patients presenting with lymphoma and without hypercalcemia. ATLL cells have an

immunophenotype that is relatively specific, so the combination of a T-cell malignancy expressing CD3, CD4, and CD25 is highly suggestive. CD25 is expressed in other B-cell and T-cell malignancies, including hairy cell leukemia,[116] classic Hodgkin lymphoma,[117] and anaplastic lymphoma kinase–positive anaplastic large cell lymphoma[47]; however, demonstration of a B-cell phenotype can readily exclude the diagnosis. Although anaplastic large cell lymphoma is usually positive for CD25, CD3 is often negative in the neoplastic cells. CD30 is strongly expressed in anaplastic large-cell lymphoma, whereas usually only a minority of ATLL cells are CD30 positive. Serologic studies for antibodies to HTLV-1 or PCR studies for HTLV-1 viral sequences can be confirmatory.

Table 32-2

ALCL, Anaplastic large-cell lymphoma; *ATLL,* adult T-cell leukemia/lymphoma; *HTLV-1,* human T-lymphotropic virus 1; *PTCL, NOS,* peripheral T-cell lymphoma, not otherwise specified; *TCR,* T-cell receptor; *T-PLL,* T-cell prolymphocytic leukemia.

To assist in epidemiologic studies of ATLL, a scoring system was proposed.[32] Clinical features counting as 1 point each are hypercalcemia, skin lesions, and a leukemic phase. Laboratory criteria, counting as 2 points each, include a T-cell phenotype, seropositivity for HTLV-1 or HTLV-2, expression of CD25 by tumor cells, and evidence of HTLV-1 or HTLV-2 sequences at the molecular level. A score of 5 or greater is a strong indication for a diagnosis of ATLL. One should bear in mind that patients from endemic areas may be seropositive for HTLV-1 but develop other lymphomas,

independent of viral positivity. Thus, demonstration of viral integration in the tumor cells is the strongest indication for a diagnosis of ATLL.

The differential diagnosis of chronic or smoldering ATLL is more diverse and includes mycosis fungoides and other cutaneous T-cell lymphomas, chronic dermatitis, and T-cell prolymphocytic leukemia. ATLL may show marked epidermotropism with Pautrier's microabscesses, mimicking mycosis fungoides. In distinction from mycosis fungoides, ATLL usually lacks an inflammatory background in the cutaneous lesions, with a higher density of neoplastic cells. Indeed, the first patient from which HTLV-1 was isolated was thought to have an aggressive form of mycosis fungoides.[1] In the peripheral blood, Sézary cells have less nuclear hyperchromasia and a cerebriform rather than a polylobated nuclear contour (**Fig. 32-16**). Further complicating the differential diagnosis was the suggestion in some studies that HTLV-1 sequences might be detected in the blood cells of some cases of otherwise typical cutaneous T-cell lymphomas.[118] Subsequent studies have largely ruled out a role of HTLV-1 in the pathogenesis of mycosis fungoides or Sézary syndrome.[119]

T-cell prolymphocytic leukemia can be CD4 positive or CD8 positive, but CD25 is usually negative. CD7 is usually positive, in contrast to ATLL cells. The cells are typically round or slightly irregular and lack the pronounced nuclear irregularities of ATLL cells. In T-cell prolymphocytic leukemia, the bone marrow biopsy usually shows extensive infiltration, whereas ATLL usually shows less bone marrow involvement than expected, based on the degree of

lymphocytosis. The bone marrow does not appear to be a site of proliferation for ATLL cells.

HTLV-2 is a retrovirus related to HTLV-1. It has not been clearly linked to any form of leukemia or lymphoma.[120] The molecular tests for HTLV-1 sequences also detect HTLV-2, so it may be necessary to rule out HTLV-2 infection in some cases. HTLV-2 has been found most often in intravenous drug users. Its clinical effects have been linked to a HAM/TSP clinical picture.

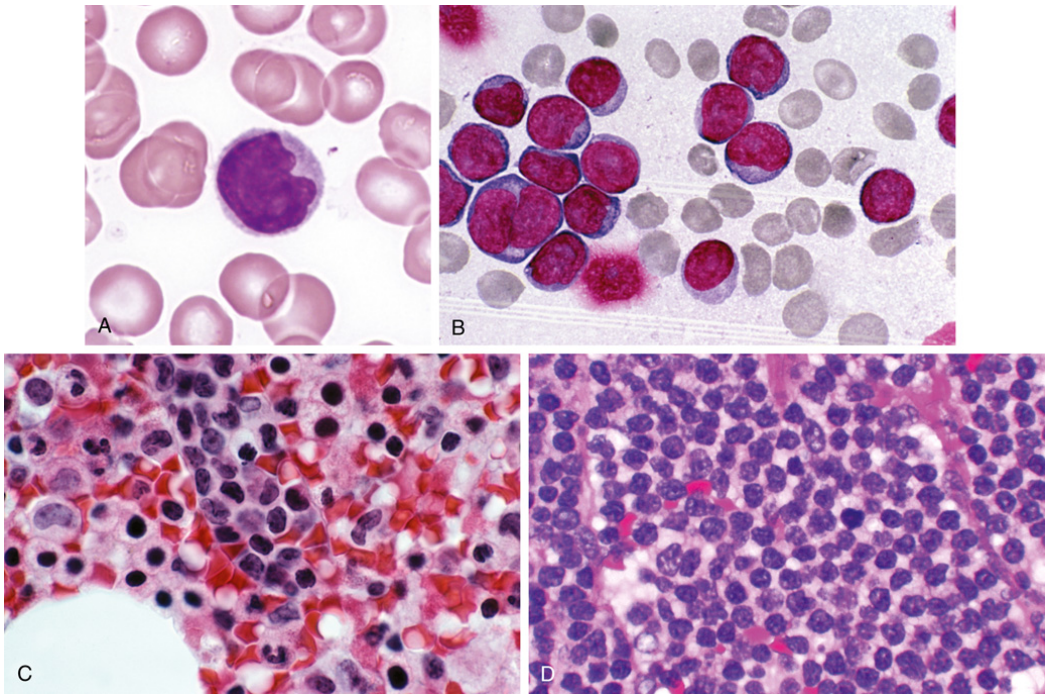

FIGURE 32-16 Differential diagnosis of adult T-cell leukemia/lymphoma (ATLL).A, Sézary cells show less nuclear hyperchromasia and more subtle nuclear changes. **B,** In T-cell prolymphocytic leukemia, lymphoid cells have round-to-oval nuclear contours and prominent nucleoli. **C,** The bone marrow is diffusely infiltrated, in contrast to ATLL, which typically shows minimal infiltration. **D,** T-cell prolymphocytic leukemia cells in the lymph node are round to slightly irregular, with central small nucleoli.

Pearls and Pitfalls

- HTLV-1 seropositivity does not prove a diagnosis of ATLL. Patients from HTLV-1–endemic areas may have antibodies to HTLV-1.
- ATLL is associated with a broad cytologic spectrum. Most cytologic variants do not have clinical significance.
- The Hodgkin-like form of ATLL may mimic classic Hodgkin lymphoma. It represents an incipient form of ATLL in which HTLV-1–infected cells are sparse. Hodgkin-like cells are EBV-positive B cells.
- Smoldering and chronic forms of ATLL may resemble chronic dermatitis.

Other T-Cell Lymphoproliferative Diseases

B-Cell Lymphomas of the Spleen

Definition

Hepatosplenic T-cell lymphoma (HSTL) is a rare, aggressive, extranodal lymphoma characterized by hepatosplenic involvement, absence of lymphadenopathy, and poor outcome. It arises from a proliferation of nonactivated, cytotoxic T cells that home to the splenic red pulp. Most cases are derived from the γδ T cells, with a small subset of αβ phenotype. The neoplastic lymphocytes are usually monomorphic and medium-sized and exhibit a unique sinusoidal infiltration of the spleen, liver, and bone marrow. Almost 40% of cases occur in settings of immune dysregulation. HSTL shows a recurrent cytogenetic abnormality, the isochromosome 7q, has a

distinct molecular signature, and harbors frequent mutations in chromatin modifiers and members of the *JAK/STAT* pathway. The disease follows an aggressive clinical course with common resistance to anthracycline-based chemotherapy regimens.

Epidemiology

HSTL is rare, representing 1.4% to 2% of all T-cell and natural killer (NK)-cell lymphomas.[1-3] This incidence is likely higher given the difficulty to achieve a correct diagnosis because of the various conditions clinically mimicking HSTL. Cases have been reported in both Western and Asian countries.[4-8] It occurs more frequently in men (male-to-female ratio of 2:1), with a median age in the fourth decade of life.[1,4-7,9-12] However, both children and elderly individuals may be affected.[5,13-15]

Etiology

The pathogenesis of HSTL is complex and not fully understood. More than half of cases occur de novo in the absence of any risk factors. However, up to 40% of patients have underlying chronic immune suppression or immune dysregulation.[5,12,16] HSTL may develop in the setting of solid organ transplantation, and it has been regarded as a late onset posttransplant lymphoproliferative disorder of host origin.[5,10,12,16-18] Cases occur also in patients with autoimmune disorders, most often Crohn's disease and less frequently rheumatoid arthritis, systemic lupus erythematosus, psoriasis, or autoimmune hepatitis. Exposure to thiopurine immunomodulators (azathioprine, 6-mercaptopurine) or tumor necrosis factor α (TNFα) antagonists (infliximab) have been

considered to be among the risk factors.[8,16,19-23] Simultaneous use of these drugs dictated by the severity of the underlying disease likely accounts for a higher risk of HSTL development.[8,24] Occasional cases have been observed after acute myeloid leukemia, Epstein-Barr virus (EBV)-positive lymphoproliferative disorders, in patients with *Plasmodium falciparum* infection,[5,25] or during pregnancy.[26] In the view of normal function of γδ T cells, these observations point toward the role of chronic antigen stimulation in settings of immune dysfunction in HSTL pathogenesis. To further support this rational, expansion and activation of γδ T cells was observed in the peripheral blood of patients infected with *P. falciparum*[27,28] or renal allograft.[29] Furthermore, an alloreactive response of human γδ T cells to various leukocyte antigen molecules has been documented in vitro.[30]

To date, no association with human T-lymphotropic virus 1 or 2, human immunodeficiency virus, human herpesvirus 8, or hepatitis C virus has been reported. One case each has been linked to hepatitis B,[31] human herpesvirus 6,[32] and parvovirus infection.[33] The vast majority of cases are negative for EBV, with exception of rare instances displaying cytologic features of transformation.[5,9,34]

Clinical Features

Patients with HSTL are predominately young adults. They commonly present with constitutional symptoms (i.e., weakness, fever, and weight loss) and abdominal discomfort related to marked splenomegaly and/or hepatomegaly, in the absence of lymphadenopathy. All patients have cytopenias, which is probably multifactorial; related to hypersplenism, bone marrow involvement,

or cytokine release; or immune mediated.[4,5,11,16,35-37] Thrombocytopenia is almost always present, and it seems to parallel disease activity.[5,24,35] Anemia is observed in ~75% of patients and neutropenia in about half of them. Seldom, manifestations of idiopathic thrombocytopenic purpura[4,38] or Coombs-negative hemolytic anemia[39] were the first symptoms. Although lymphocytosis is uncommon, a minor population of atypical lymphoid cells can be identified by careful examination of blood smears or by flow cytometry in more than half of patients.[5,24,35,36,40] An overt leukemic picture, rare at presentation, can be seen in advanced disease.[5,40] Hemophagocytic syndrome may occur and is associated with a fulminant clinical course.[5,11,13] Other laboratory findings include elevated levels of lactate dehydrogenase (LDH), β2-microglobulin, and abnormal liver function tests[4,5,11,16,37]

Computed tomography (CT) typically shows hepatosplenomegaly without distinct lesions and absence of lymphadenopathy. ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET)/CT may reveal diffuse and intense uptake of spleen, liver, and bone marrow, with normal FDG activity of the lymph nodes.[41]

Virtually all patients have Ann Arbor stage IV disease as a result of bone marrow involvement. They frequently have a performance status >1 and present with two or three adverse risk factors of the age-adjusted International Prognostic Index, which places them in the high-risk group.[5,11]

Morphology

The diagnosis of HSTL is based on histopathologic and immunophenotypic evaluation of the involved tissue. The atypical

cells are preferentially located in the cords and sinusoids of the splenic red pulp, bone marrow, and liver. Lymph nodes are rarely involved at presentation. In the past, the diagnosis was often made on splenectomy. Currently, bone marrow biopsy is the recommended diagnostic procedure.[42] Although examination of the bone marrow aspirate allows for cytologic, flow cytometry phenotyping, and cytogenetic analysis, it alone does not suffice for the diagnosis.[5,10,40] Though liver biopsy is recommended by the National Comprehensive Cancer Network (NCCN) guidelines,[42] it is less useful in clinical practice given the morphologic finding of HSTL that overlap with other lymphomas or conditions.

Spleen

The spleen is often markedly enlarged (common weight 1000-3500 g), with a homogeneous red-purple cut-surface and no gross lesions identifiable macroscopically. Hilar lymph nodes are not increased in size.

The neoplastic infiltrate diffusely involves and expands the splenic red pulp, without architectural destruction, whereas the white pulp is markedly reduced or lost (**Fig. 33-1A**). The atypical cells are frequently seen within the sinusoids and, to a variable extent, within the cords of the red pulp. Dilated sinusoids filled with sheets of neoplastic lymphoid cells are the typical features (**Fig. 33-1B**). The cells are medium-sized, with a monotonous appearance, and they show round or slightly irregular nuclei with loosely condensed chromatin and inconspicuous nucleoli. The cytoplasm is moderately abundant and usually agranular (**Fig. 33-1C**). Seldom, the atypical lymphocytes range from small to large to pleomorphic.[10,11,43]

Mitotic figures are rare. A few small lymphocytes may be admixed, and plasma cells are uncommon. Histiocytes may be numerous and sometimes show erythrophagocytosis either at presentation or during the disease course (**Fig. 33-1C**).

Although usually not enlarged, splenic hilar lymph nodes commonly manifest some degree of lymphomatous involvement confined to the sinuses or perisinusal areas, without destruction of the normal architecture.[5,35,44]

Liver

Histologic involvement of the liver is fairly constant at presentation. It leads to hepatomegaly, frequently without discrete lesions.[4,5,24,37] The neoplastic lymphoid infiltrate commonly shows a sinusoidal pattern (**Fig. 33-1D**), which can lead to pseudopeliotic lesions or perisinusoidal fibrosis.[36,45] The atypical lymphocytes may be subtle on slides stained with H&E (hematoxylin and eosin) and may be only highlighted by immunohistochemical stains with T-cell antigens. Marked portal and periportal infiltrate with sinusoidal extension have been uncommonly reported.[11,36]

Bone Marrow

Bone marrow involvement is almost constant when trephine biopsies are carefully investigated by combined histologic and immunohistochemical studies.[5,10,11,40,43,46] At presentation, the bone marrow is usually hypercellular with trilineage hyperplasia (**Fig. 33-2A**). It may show mild dysmyelopoiesis, which can mislead to diagnosis of myelodysplastic syndrome in settings of peripheral cytopenia. Neoplastic cells selectively involve and expand the bone

marrow sinusoids, a feature highly characteristic and thus an essential diagnostic criterion for HSTL. The lymphoid infiltrate is often discrete and subtle and may be difficult to recognize based on morphology. The atypical lymphocytes are small to medium-sized and show an “Indian file” or aggregate-like distribution within variably distended bone marrow sinusoids.[5,10,11,35,40,43,46] This pattern is highlighted by CD3 immunostaining (**Fig. 33-2B**).

In addition, careful examination of the bone marrow aspirate and peripheral blood smear may identify a minor population of atypical lymphoid cells. They are often intermediate-sized with irregular nuclear contours, dispersed chromatin, inconspicuous nucleoli, and a moderate amount of light-blue cytoplasm, occasionally showing vacuoles (**Fig. 33-3A**) or fine azurophilic granules.[47] The atypical cells may resemble hairy cells,[48] lymphoblasts with “hand mirror” cytoplasmic projections,[47] or may even cluster, mimicking a metastasis.[49] Histiocytic cell phagocytosis of red blood cells or other hematopoietic precursors can be observed.

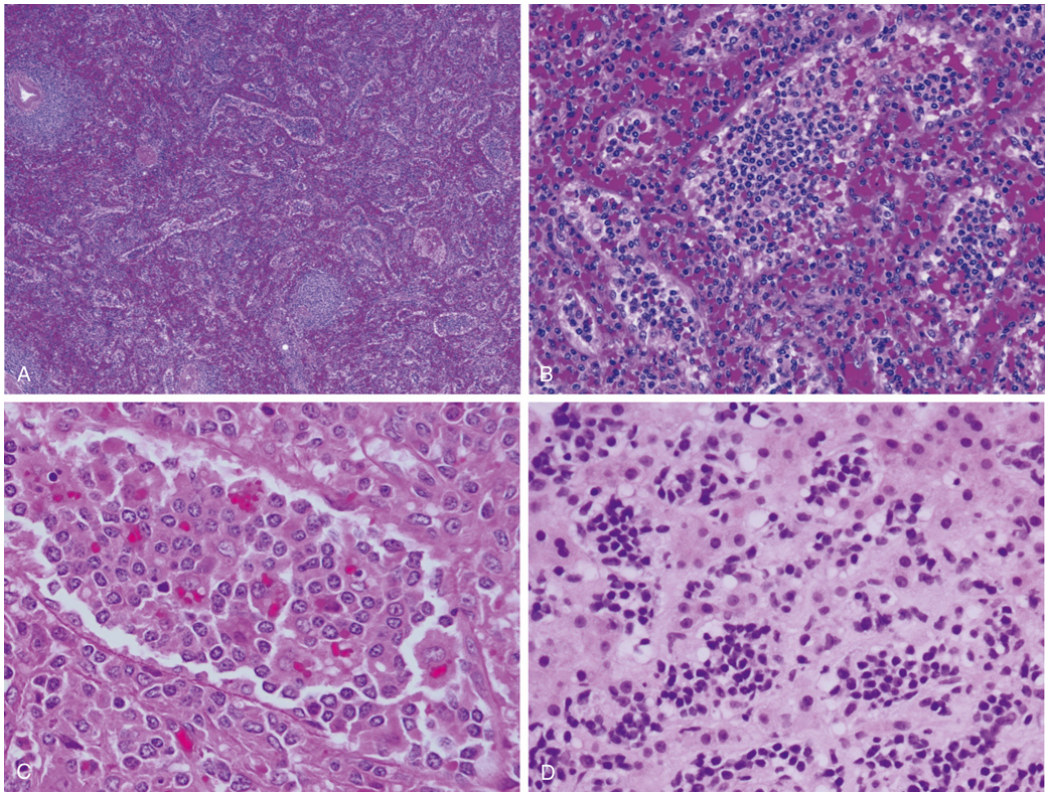

FIGURE 33-1 Histopathology of spleen and liver involvement by hepatosplenic T-cell lymphoma.A, The spleen shows expansion of the red pulp and atrophic nodules of the white pulp. **B,** The splenic sinusoids are filled and dilated by atypical medium-sized lymphocytes. **C,** They display round nuclei with finely dispersed chromatin and a moderate amount of pale eosinophilic cytoplasm. Hemophagocytic macrophages are also seen. **D,** The neoplastic infiltrate predominantly involves the liver sinusoids.

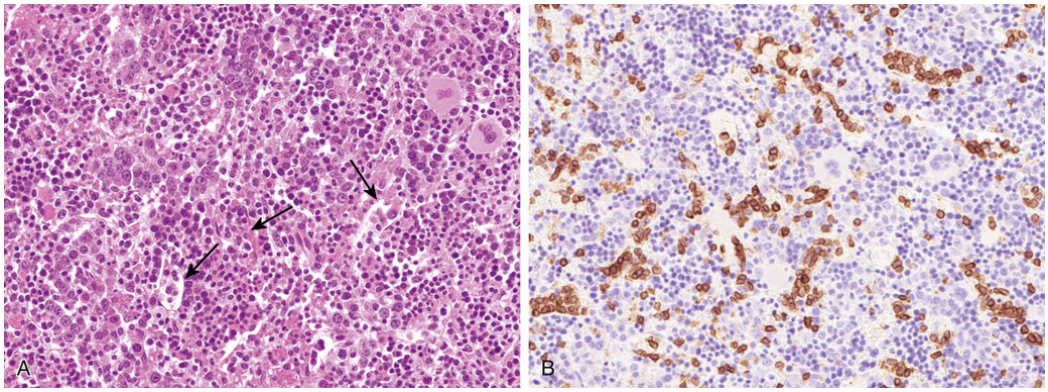

FIGURE 33-2 Bone marrow involvement by hepatosplenic T-cell lymphoma.A, There is a subtle atypical lymphoid infiltrate in a hypercellular marrow. The *arrows* indicate the "Indian file" sinusoidal distribution of medium-sized lymphocytes, which are highlighted with CD3 immunostaining **(B).**

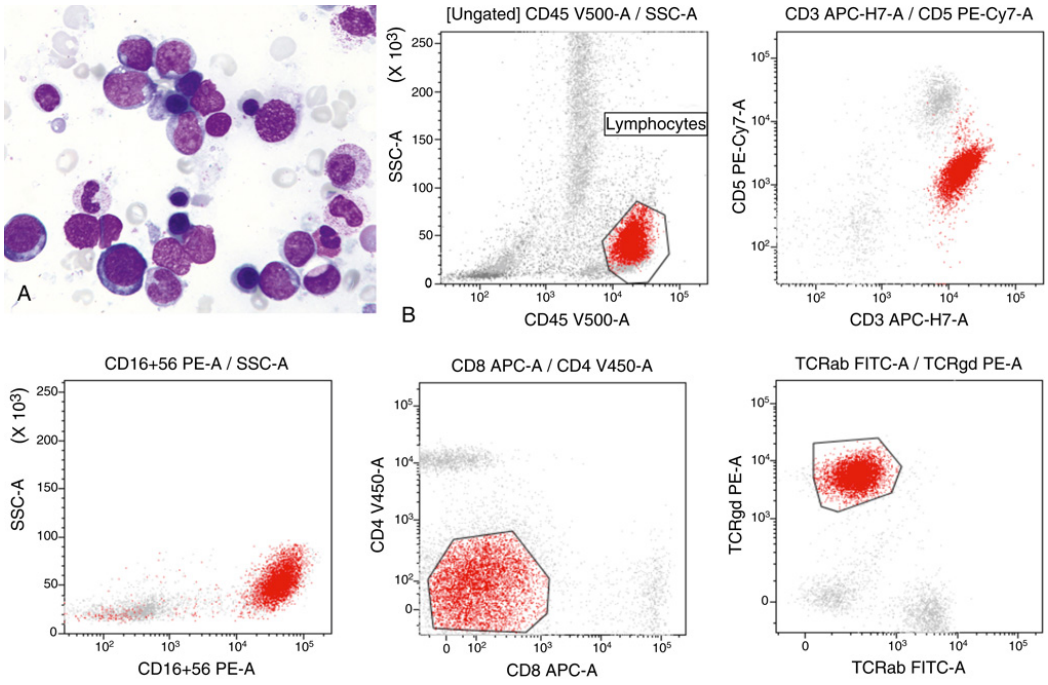

FIGURE 33-3 Bone marrow aspirate and phenotype of hepatosplenic T-cell lymphoma by flow cytometry.A, Wright-Giemsa–stained smear shows intermediate-sized lymphocytes with irregular nuclear contours, small nucleoli, and a moderate amount of cytoplasm, occasionally showing vacuoles. **B,** By multiparametric flow cytometry, these cells are found in the CD45 lymphocytes gate and show the following phenotype: $CD3^+$, $CD5^-$, $CD4^-$, $CD8^-$, $CD16^+$, $CD56^+$, $TCR\gamma\delta^+$. Figs. 33-3 and 33-4 summarize the bone marrow findings in a 5-year-old boy who presented with severe pancytopenia. Courtesy of Dr. Caroline Mayeur Rousse and Dr. Anne Galoisy, Hautepierre University Hospital, Strasbourg, France.

Cytologic Variants

Overall, the cytologic appearance of neoplastic lymphocytes shows little variation among patients at presentation. The cells are usually monomorphic and small to medium-sized. Blastoid or pleomorphic medium-to-large cells have been occasionally observed at diagnosis but more often occur with disease progression.[5,11,40,43,50,51] These cytologic variants manifest a similar tissue distribution in sites involved by HSTL. However, in advanced disease, the bone marrow infiltration may extend beyond the sinuses, resulting in an interstitial (**Fig. 33-4A**) or diffuse pattern, and the neoplastic cells become larger.

Phenotype

All HSTL cases show immunohistochemical staining with T-cell antigens and are negative for B-cell–associated markers on formalin-fixed paraffin embedded tissue (FFPE) sections. The neoplastic cells are usually CD2+, CD3+, CD5−, CD7+/−, and CD4−/CD8− (**Fig. 33-4C**) with a small subset of cases that are CD4−/CD8+.[4,5,11,16,36,37,46,50,52] Among the NK-cell–associated markers, most cases express CD56 (**Fig. 33-4D**), some are CD16-positive, and CD57 is usually negative. All cases have a cytotoxic phenotype with typical granular cytoplasmic expression of cytotoxic molecule T-cell intracellular antigen 1 (TIA-1) (**Fig. 33-4E**) and serine protease granzyme M.[53] Most cases of HSTL are negative for granzyme B and perforin, consistent with mature, nonactivated cytotoxic T-cell phenotype.[35,54,55] Cytotoxic activity has been demonstrated in few cases in addition to CD52 positivity.[11,56] Expression of killer immunoglobulin-like receptors (KIRs) and, to a

lesser degree, CD94/NKG2A seems to be a common feature.[43,57-59] HSTL is negative for the activation antigens CD25 and CD30. A majority of cases express T-cell receptor (TCR)γδ, as shown by monoclonal antibodies reactive with TCRγ or TCRδ available for routine use on FFPE tissue samples (**Fig. 33-4B**).[55,60,61] Most γδ HSTLs seem to arise from a subset of γδ T cells of *Vδ1* usage, as shown by molecular studies and δTCS-1 antibody expression.[5,16,50,62-64] However, approximately 20% of cases have TCRαβ (βF1+/TCRγ−/δ−) and <5% show a TCR "silent" phenotype (βF1+/TCRγ−/δ−) either at presentation or at relapse.[10,11,36,43,59,60,65] They are classified together with the more common γδ form of the disease based on overlapping clinicopathologic, cytogenetic, and molecular features.[11,59,65]

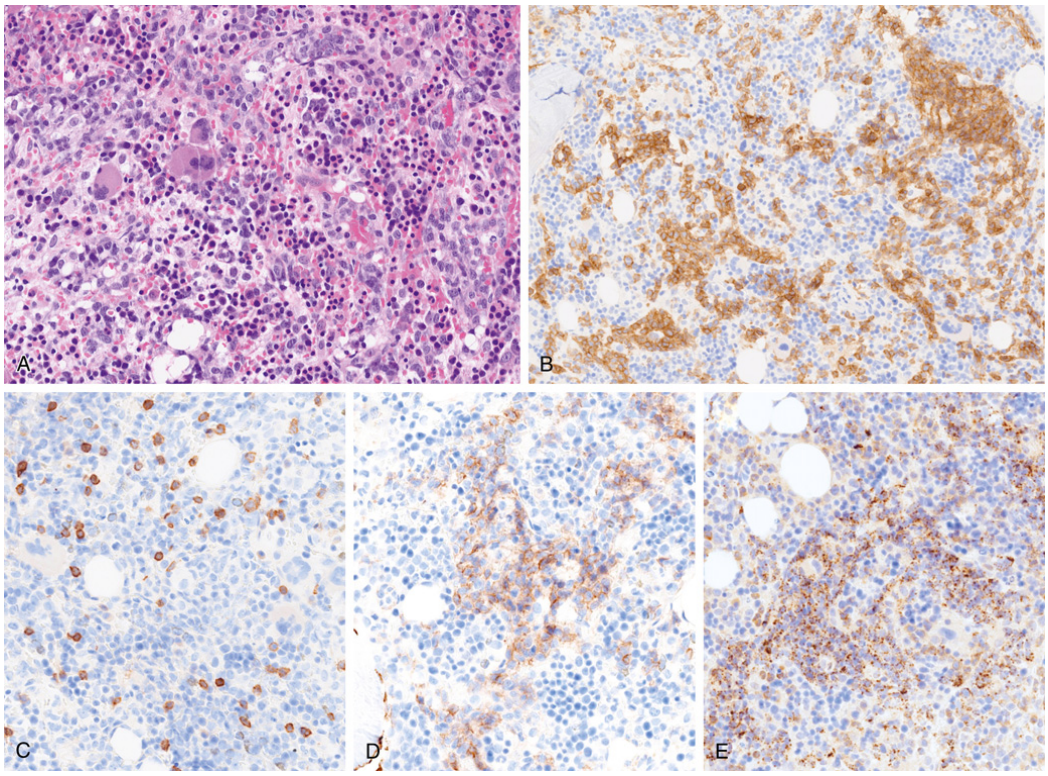

FIGURE 33-4 Overt bone marrow involvement by hepatosplenic T-cell lymphoma.A, The atypical lymphocytes distend the bone marrow sinusoids and slightly spread in the interstitium. They express TCRδ **(B)** and are $CD5^-$ **(C)**, $CD56^+$ **(D)**, and TIA-1^+ **(E)**. Figs. 33-3 and 33-4 summarize the bone marrow findings in a 5-year-old boy who presented with severe pancytopenia.

Although monoclonal antibodies against β, γ, or δ chains of TCR can be used on FFPE tissues, flow cytometric analysis of bone marrow aspirates is highly recommended, enabling not only a complete immunophenotyping of neoplastic cells (**Fig. 33-3B**), but also access to neoplastic cells for cytogenetic and molecular studies.

Cytogenetic and Molecular Findings

Cytogenetics

Recurrent chromosomal abnormalities have been identified in HSTL, supporting its diagnosis in difficult cases. The most frequent genetic alterations, which frequently co-occur, are isochromosome 7q [i(7)(q10)] and trisomy 8, detected in up to 80% and 50% of γδ HSTL cases, respectively (**Fig. 33-5**).[4,5,10,11,13,16,36,58,60,66-70] Of note, i(7)(q10) has also been reported in HSTL expressing TCRαβ.[10,36,43,50,60,65,68] Other less common alterations include ring 7 [r(7)], loss of chromosomes Y, 21, 10p, and 11q14, and gain of chromosome 1q.[60,69,71] The relevance of these abnormalities to the HSTL pathogenesis is still unknown. However, i(7)(q10) is regarded as the primary genetic event, and trisomy 8, r(7), and loss of chromosome Y are likely acquired during disease progression.[67,68] Both i(7)(q10) and r(7) lead to amplification of the 7q22.11q31.1 locus and 7p22.1p14.1 loss. These changes associate an overexpression of *ABCB1, RUNDC3PPP1R9A, and CHN2*/β2-chimerin genes, which may be responsible for the intrinsic drug resistance of neoplastic cells and their growth advantages.[69] Although i(7)(q10) characteristically occurs in HSTL, it is not specific for this entity. It has also been reported in acute myeloid and lymphoblastic leukemia, myelodysplastic syndrome, Wilms' tumor, and in rare cases of extranodal NK/T-cell lymphoma, nasal type, and anaplastic large cell lymphoma.[72]

Molecular Features

Irrespective of their γδ-phenotype or αβ-phenotype, HSTLs show a clonal rearrangement of the TCRγ chain gene (TRG) by polymerase

chain reaction (PCR)-based study. Often, a biallelic clonal rearrangement of TCRδ chain gene is demonstrated by Southern blot or PCR analysis, in accordance with the γδ-genotype of neoplastic T cells.[5,59,63,64] Unproductive rearrangements of the β chain (TRB) have been reported in some γδ HSTLs, as in the corresponding normal γδ T cells.[63] In addition, the illegitimate somatic rearrangements of both TRG and TRB loci may lead to formation of r(7), as shown by high-resolution array comparative genomic hybridization (CGH) studies.[69] The αβ HSTL cases show a clonal rearrangement of TRB in addition to TRG.[36,39]

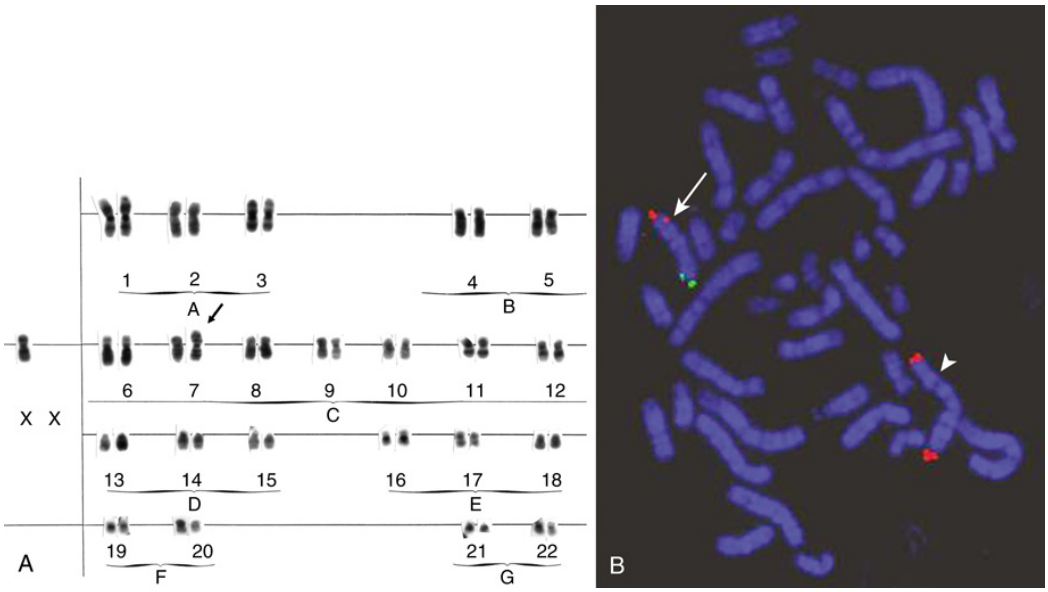

FIGURE 33-5 Cytogenetics of hepatosplenic T-cell lymphoma.A, Representative karyotype with isochromosome 7q [i(7)(q10)], indicated by the *arrow*. **B,** Example of abnormal metaphase with i(7)(q10) after fluorescence in situ hybridization subtelomeric probes for 7p *(green)* and 7q *(red)*. The *arrow* and *arrowhead* show normal chromosome 7 and i(7)(q10), respectively. Note i(7)(q10)-associated loss of the 7p signal and gain of the 7q signal. HSTL presents a gene expression profile (GEP) signature distinct from other T-cell lymphomas and similar to γδ and αβ HSTL cases. It is characterized by overexpression of genes encoding NK-related antigens, such as *KIR*s.[59,73,74] In addition, a high expression of sphingosine-1-phosphatase receptor 5 *(S1PR5)*, involved in cell

trafficking, has been reported, which might explain the peculiar sinusoidal pattern with no significant leukemic phase seen in HSTLs.[59] Furthermore, overexpression of *SYK* with sensitivity of HSTL cell lines to Syk inhibitors has been underlined in this entity.[59] Nevertheless, active expression of oncogenes *VAV3, MYBL1,* and multidrug resistance 1 *(MDR-1)* and downregulation of tumor suppressor gene *AIM1* were highlighted as potential players in the pathobiology and aggressiveness of HSTL.[59]

Sequencing studies have revealed highly recurrent mutations in epigenetic regulators and members of the JAK/STAT and PI3K-signaling pathways, proving a framework for innovative therapies in HSTL.[55,60,75] More than 60% of patients manifest genetic changes in chromatin modifying genes such as *SETD2, INO80, TET3,* and *SMARCA2*.[60] In addition, frequent missense mutations in *STAT5B* and, less common, *STAT3* and *PIK3CD* have been reported in 30% and 10% of cases, respectively.[60,70,75] These alterations have been linked to HSTL pathogenesis. Loss of function mutations of tumor suppressor gene *SETD2* and gain-of-function mutations of *STAT5B, STAT3,* and *PIK3CD* genes increase proliferation and activate signalling pathways critical for cell survival in HSTL.[60] However, these mutations are not unique to HSTL and can occur in other mature, cytotoxic T-cell and NK-cell lymphomas.[52,75-83] Conversely, HSTL lacks *RHOA* mutations and rarely exhibits *CD28* and *CCR4* gene alterations, which are commonly seen in other T-cell neoplasms.[60]

Epstein-Barr Virus Studies

By in situ hybridization with EBV-encoded small RNA (EBER) probes, an association with EBV has been found in exceptional cases of HSTL with cytologic features of transformation, suggesting that EBV might occur as a secondary event.[5,34]

Postulated Cell of Origin

The normal cell counterpart of HSTL has not been clearly identified. It is thought to derive from a subset of cytotoxic T cells, mostly of TCRγδ usage, involved in innate immunity.[84] The γδ T cells are the prototype of "unconventional" T cells, activated in a major histocompatibility complex (MHC)-independent manner. They are derived from CD4-negative CD8-negative (double negative) thymic precursors and represent <5% of mature circulating T cells in healthy adults. These cells are enriched within the intraepithelial regions of the skin and mucosa and in the red pulp of the spleen, serving as first line of defense against pathogens and transformed cells. Although most peripheral-blood γδ T cells express Vδ2 TCR, Vδ1 T cells are higher within tissue, including the spleen.[85,86] This likely explains the Vδ1 TCR detection in most γδ HSTLs.[5,62-64] Furthermore, this lymphoma is thought to arise from cytotoxic T cells of memory phenotype, given the expression of KIR antigens, which are normally encountered on a subset of memory cytotoxic T cells and on NK cells.[58] Of note, KIR-positive normal αβ and γδ cytotoxic T cells typically express a single KIR isoform. However, both γδ and αβ HSTL variants frequently express multiple KIR isoforms.[57-59,73,74] This might link HSTL pathogenesis to chronic antigenic stimulation, which can trigger the expression of multiple KIR isoforms.[5]

CLINICAL Course

The disease has an aggressive clinical course, with most patients dying of lymphoma within 2 years of diagnosis.[4,5,11,16,37,87] In a large population-based analysis, HSTL was one of the highest-risk PTCL subtypes.[88] An indolent phase prior to a more aggressive disease has been reported in some patients.[10,89] Male gender, chronic immunosuppression, elevated serum LDH or bilirubin level (≥1.5 mg/dL), and TCRαβ have been cited as poor prognostic indicators.[4,5,11,16,36,37,87,90] Relapse or disease progression occurs in initially involved sites (i.e., spleen, if splenectomy was not performed, bone marrow, liver) and does not result in lymphadenopathy, thus reinforcing the peculiar homing of the neoplastic cells. In exceptional cases, relapses may occur in skin, mucosa, and meninges. Few patients manifested a significant leukemic phase.[5]

Therapy

Treatment approaches have been highly heterogeneous in HSTLs, and its rarity has hampered prospective clinical trials from being undertaken and standard, effective approaches from being proposed. Disappointing results with early relapses were seen after anthracycline-containing (CHOP [cyclophosphamide, doxorubicin, vincristine, and prednisone] or CHOP-like) regimens.[5,12,16,37] According to the NCCN guidelines, the use of nonanthracycline-based regimens such as ICE (ifosfamide, carboplatin, etoposide) or DHAP (cytosine arabinoside, cisplatin, dexamethasone) is recommended, followed by allogeneic hematopoietic stem cell transplantation (HSCT) when complete remission is achieved.[42]

Lower rates of relapse and higher efficacy were seen after allogeneic HSCT compared with autologous HSCT, which is probably related to the graft-versus-lymphoma effect conferred by the former.[91-94] Given its in vitro selective cytotoxic effect on malignant γδ T cells, 2′deoxycoformycin (pentostatin) has also been suggested as an active agent.[89,95-98]

Novel therapeutic options are needed to improve the outcome of patients with HSTL in the future. Genetic studies have pointed toward recurrent dysregulation of oncogenic pathways such JAK/STAT and *PI3KCD* and chromatin modifying genes, including *SETD2,* which are potentially targetable.[60] *SETD2*-mutated HSTL cells may be sensitive to WEE1 inhibitors.[99,100] Similarly, it is questionable whether Syk inhibitors or hypomethylating agents could be useful to control this disease.[59]

Differential Diagnosis

The major diagnostic features of HSTL are listed in **Box 33-1**. The differential diagnosis includes other lymphomas, mainly of T-cell or NK-cell derivation, which present with hepatosplenic disease and infiltration of the splenic red pulp. Particularity challenging is the distinction of HSTL from T-cell large granular lymphocytic leukemia and aggressive NK-cell lymphoma/leukemia. Among the B-cell neoplasms, hairy cell leukemia and splenic diffuse red pulp small B-cell lymphoma must be ruled out. The discriminatory features between these entities are summarized in **Table 33-1**. HSTL should also be distinguished from benign peripheral-blood γδ T-cell expansions observed in various benign settings such as infections or autoimmune diseases.[101,102]

Box 33-1 Major Diagnostic Features of Hepatosplenic T-Cell Lymphoma

- Aggressive disease, B symptoms
- Splenomegaly (massive) without nodules
- Hepatomegaly
- No lymphadenopathy
- Thrombocytopenia, frequent anemia, leukopenia
- No lymphocytosis
- Monomorphic small to medium-sized cells
- Sinusoidal pattern of infiltration in the bone marrow, spleen, and liver
- $CD3^+$, $CD5^-$, $CD4^-/CD8^-$, $CD56^{+/-}$ phenotype
- Nonactivated cytotoxic profile (TIA-1^+, granzyme B^-, perforin$^-$)
- Absence of Epstein-Barr virus
- Isochromosome 7q (50%–70%)
- *STAT5B* mutations (30%), *SETD2* mutations (25%)

Aggressive NK-Cell Lymphoma/Leukemia

Aggressive NK-cell lymphoma/leukemia (ANKL) is a rare systemic NK neoplasm, described commonly in young to middle-aged adults mainly of Asian ethnicity.[103-105] It represents a major differential diagnosis of HSTL given overlapping clinical, cytologic,

immunophenotypic, and molecular features. Both entities present with hepatosplenomegaly, B-symptoms, cytopenia, and aggressive behavior. As in HSTL, in ANKL, the splenic red pulp and sinusoids of the liver are infiltrated by atypical lymphocytes $CD2^+$, $CD5^-$, $CD56^+$, $CD4^-/CD8^-$, showing JAK/STAT pathway activation, epigenetic dysregulation, and impairment of TP53 and DNA repair.[103-107] However, as opposed to HSTL, the atypical cells in ANKL are more pleomorphic, display prominent cytoplasmic azurophilic granules, and typically show a leukemic spread. In addition, the bone marrow demonstrates a variable degree of interstitial or patchy atypical lymphoid infiltrate, without a sinusoidal predilection. Furthermore, the neoplastic lymphocytes in ANKL are of NK-cell derivation. They are typically negative for *surface* CD3 by flow cytometry, show an activated cytotoxic phenotype, and lack TCR expression and clonal gene rearrangement. Finally, EBV is detected in the neoplastic cells of most patients with ANKL, with only rare exceptions.[108] ANKL is consistently associated with hemophagocytic syndrome and follows a fulminant course with a median survival of approximately 2 months.[103-105,109]

T-Cell Large Granular Lymphocytic Leukemia

T-cell large granular lymphocytic leukemia (T-LGLL) is a chronic, indolent lymphoproliferative disorder with clinical and laboratory manifestations often distinct from those observed in HSTL.[110,111] It usually affects older patients who are either asymptomatic or present with a moderately enlarged spleen and symptoms related to autoimmune disorders or to neutropenia and/or anemia. Dissimilar to HSTL, T-LGLL manifests with a leukemic blood picture. The

neoplastic cells typically display azurophilic granules within the cytoplasm and show CD3+, CD8+, CD57+, TCRαβ+, $CD56^-$, and activated cytotoxic phenotype.[110-112] They exhibit frequent *STAT3* mutations[77,113] and lack i(7q).[114] However, rarely, T-LGLL affects younger patients, shows a CD4-negative CD8-negative and a TCRγδ-positive phenotype.[11,110,114,115] Some cases have *STAT5B* gene mutations and follow an aggressive clinical course,[116] making challenging the distinction from HSTL. Although histopathology is rarely required for T-LGLL diagnosis, the pattern of neoplastic cell distribution within the splenic red pulp and sinusoids of the liver may overlap with that observed in HSTL. However, in T-LGLL, the bone marrow biopsy often demonstrates a mixed interstitial and intrasinusoidal lymphoid infiltrate without notable atypia, blending with hematopoietic cells. In addition, nonneoplastic lymphoid nodules composed of a variable mixture of CD20-positive B lymphocytes and CD4-positive T lymphocytes are frequently associated.[112,117,118]

Other T-Cell Lymphoproliferative Diseases

Other T-cell lymphoproliferations of γδ T-cell derivation or with shared clinical features with HSTL should also be considered in the

differential. As previously mentioned, demonstration of γδ T-cell phenotype is not specific to HSTL. Beside T-LGLL and T-lymphoblastic lymphoma/leukemia, a subset of extranodal cytotoxic T-cell lymphomas occurring predominately at mucosal sites such as the nasopharynx, intestine, and skin are also of γδ T-cell derivation.[9,10,61,86,119,120] This is consistent with the normal γδ T-cell distribution,[84] functioning as mature, activated cytotoxic T cells, ensuring the first line of immune defence in the mucosa and skin. Therefore, these non-hepatosplenic γδ T-cell lymphomas constitute a subgroup of activated cytotoxic T-cell neoplasms with mainly extranodal presentation. Despite the shared γδ phenotype, they are classified distinctively as extranodal NK-cell or T-cell lymphoma nasal-type, monomorphic epitheliotropic intestinal T-cell lymphoma, or primary cutaneous γδ T-cell lymphoma.[111] This suggests that their "identity" relies rather upon the site of origin, the functional properties of the corresponding T cells, and the specific pathogenic cues than on their precise γδ T-cell phenotype.[9,61,86,119] Although these lymphomas may show splenic and bone marrow involvement, their distinction from HSTL is less challenging given differences in the clinical and immunophenotypical features.

Patients with chronic active EBV infection or systemic EBV-positive T-cell lymphoma of childhood can present with symptoms mimicking HSTL, such as fever, hepatosplenomegaly, and cytopenia. However, the bone marrow biopsy depicts usually interstitial infiltrate of small to medium-sized EBV-positive T cells or NK cells without significant cytologic atypia.

B-Cell Lymphomas of the Spleen

Among the B-cell neoplasms, certain primary splenic lymphomas are relevant to the differential diagnosis of HSTL given their clinical presentation as hepatosplenic disease and/or pattern of neoplastic cell distribution within the splenic red pulp, liver, or bone marrow. These include hairy cell leukemia, splenic marginal zone lymphoma (SMZL), and splenic diffuse red pulp small B-cell lymphoma. Despite diffuse involvement of splenic red pulp, hairy cell leukemia differs from HSTL by its peculiar cytologic appearance on blood smears, diffuse interstitial bone marrow involvement with notable reticulin fibrosis, B-cell phenotype (typically $CD103^+$, $CD25^+$, $CD11c^+$, Annexin $A1^+$, and $CD123^+$), and *BRAF*-V600E gene mutation.[111,121] As in HSTL, splenic diffuse red pulp small B-cell lymphoma shows splenomegaly with red pulp involvement and usually elective sinusoidal bone marrow spread of small atypical lymphocytes. A sinusoidal bone marrow involvement by small B cells has also been reported in SMZL, but it appears less frequent and is usually associated with an interstitial or nodular bone marrow infiltration. These later lymphomas have a B-cell phenotype and follow an indolent clinical course.[111,122,123]

Overall, the selective sinusoidal bone marrow involvement by the neoplastic lymphocytes is a distinctive feature of HSTL, contrasting with the interstitial and/or nodular pattern of infiltration observed in most B-cell, T-cell, and NK-cell lymphoproliferations. In addition, demonstration of CD3+, CD5−, CD4−/CD8−, $CD56^+$, TIA-1+, granzyme B^-, and EBV^- phenotype of atypical T-cell infiltrate in the bone marrow specimens provides strong evidence for HSTL diagnosis.

Pearls and Pitfalls

- Clinical presentation of HSTL is not typical for lymphoma. It shares symptoms with many systemic diseases:
  - Unexplained weakness with fever and splenomegaly
  - No overt tumoral syndrome with no lymphadenopathy
  - Thrombocytopenia and anemia, occasionally leading to misdiagnosis of idiopathic thrombocytopenic purpura or Coombs-negative hemolytic anemia
- Diagnosis is based on careful examination of the bone marrow biopsy (± aspirate):
  - Look for elective and constant sinusoidal infiltration ("Indian file" or aggregates dilating sinuses)
  - Identification may be difficult in the common context of hypercellular marrow (not to be misinterpreted as myelodysplastic syndrome)
  - CD20 and CD3 immunostainings provide better recognition and are recommended in patients with unexplained splenomegaly
  - Aspirate smears are highly useful for a complete immunophenotypic analysis by flow cytometry, cytogenetic, and molecular studies
- Splenectomy is no longer required for diagnosis.
- Demonstration of a γδ T-cell origin is recommended. Though most HSTL have a γδ phenotype, rare cases with an αβ phenotype have been reported.

- Atypical features in some HSTL cases include an indolent initial phase, a cytologic pleomorphism (medium/large cells), granzyme B staining (partial), and circulating cells in late phase of disease or relapse.
- Integration of clinical, pathologic, and phenotypic data with genetic changes is sometimes needed to distinguish HSTL from ANKL and T-LGLL.

Chapter 34: Peripheral T-Cell Lymphoma, Not Otherwise Specified

Laurence de Leval

OUTLINE

Definition

SYNONYMS AND RELATED TERMS

Epidemiology

Clinical Features

Morphology

Immunophenotype

Genetic and Molecular Characteristics

- **Antigen Receptor Genes**
- **Genetic Abnormalities**

Variants and Subgroups

- **Lymphoepithelioid Variant of PTCL, NOS**
- **Cytotoxic Molecule– Positive PTCL, NOS**

Cell- of- Origin Subgroups

Extranodal Peripheral T- Cell Lymphoma, Not Otherwise Specified

Prognosis and Predictive Features

PRIMARY NODAL EPSTEIN-BARR VIRUS–POSITIVE T/NATURAL KILLER–CELL LYMPHOMA

DIAGNOSTIC APPROACH TO PERIPHERAL T-CELL LYMPHOMA, NOT OTHERWISE SPECIFIED AND DIFFERENTIAL DIAGNOSES

Peripheral T-Cell Lymphoma, Not Otherwise Specified Versus Reactive Lymphoid Hyperplasia

Peripheral T-Cell Lymphoma, Not Otherwise Specified With Reed-Sternberg–Like Cells

Lymphoepithelioid Variant of Peripheral T-Cell Lymphoma, Not Otherwise Specified (Lennert Lymphoma)

CD30-Positive Peripheral T-Cell Lymphoma, Not Otherwise Specified

Definition

Peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS) encompasses per definition all mature (peripheral) T-cell neoplasms

lacking specific features that qualify for any of the other better defined "specific" entities of postthymic T-cell lymphoma/leukemia.[1-3] The definition is unchanged from the previous World Health Organization (WHO) classifications, and PTCL, NOS remains a diagnosis of exclusion. Importantly, recent advances have led to reclassification of subsets of former PTCL, NOS and have narrowed down the diagnostic criteria. A notion already introduced in the revised 4th ed. of the WHO Classification (2017) is that PTCL, NOS excludes nodal/systemic PTCLs with a follicular helper T-cell (TFH) phenotype, defined by the expression of at least two TFH markers, which are now diagnosed as a TFH lymphoma subtype.[1-3] In addition, primary nodal Epstein-Barr virus (EBV)–positive T/natural killer (NK)-cell lymphoma is no longer a variant of PTCL, NOS, but recognized as an entity in the 2022 International Consensus Classification (ICC) and in the WHO 5th ed. PTCL, NOS is still viewed as a heterogeneous group of neoplasms, which likely do not constitute a single entity, waiting for further individualization of meaningful subgroups and substratification. Although efforts have been made in that direction, and there is growing evidence to substantiate the rationale for molecular or functional subgrouping among PTCL, NOS, neither the ICC nor the revised WHO 5th ed. have yet recognized new diagnostic subtypes.

SYNONYMS AND RELATED TERMS

None.

Epidemiology

PTCL, NOS, formerly PTCL unspecified,[4] has been for decades reported as the most frequent PTCL entity. In the International T-cell

Project, which collected PTCL cases from Europe, Asia, and North America between 1990 and 2002, PTCL, NOS was the most prevalent systemic PTCL entity worldwide, accounting for 26% PTCLs,[5] markedly above TFH lymphoma of angioimmunoblastic-type (AITL) (18.5% of the cases). PTCL, NOS was relatively more common in North America and in Europe (34% of the cases) compared with Asia (22%), where other PTCL entities (EBV-associated NK/T-cell neoplasms and human T-cell lymphotropic virus 1 (HTLV1)-associated leukemia/lymphoma) are more prevalent.

In recent years, with the refinement of diagnostic criteria, better knowledge of PTCL entities, and the expansion of the spectrum of TFH lymphomas, the reported prevalence of PTCL, NOS has tended to decrease. In a project conducted by the North American PTCL study group to evaluate the diagnostic workup of PTCL, based on 336 cases collected from several institutions, PTCL, NOS was the second most common diagnosis (26% of the cases), side by side with AITL (27% of the cases).[6] It is likely that the high prevalence of PTCL, NOS reported in preceding times was caused by incomplete phenotypic characterization, and particularly lack of systematic investigation for TFH markers.[7] Based on an analysis of the French lymphoma registry (Lymphopath) and a review of >32,000 noncutaneous lymphomas between 2010 and 2013, PTCL, NOS accounted for 27% of the cases, and was largely outnumbered by AITL (36% of the cases).[8,9] In a multinational multicentric registry study prospectively conducted in Asia between 2016 and 2019, based on 486 PTCL patients, PTCL, NOS was the third most frequent entity (21% of the cases), after extranodal NK/T-cell lymphoma, nasal type, and AITL.[10]

Clinical Features

The disease tends to be diagnosed in middle-aged to older adults at a median age of 60 years, and is very rare in children, adolescents, and young adults.[11] There is a male predominance in most published series.[12,13] PTCL, NOS typically involves lymph nodes, but may primarily present in any extranodal site. Most of the patients (about 70%) have disseminated disease (stage III or IV) at the time of diagnosis with infiltrates in the bone marrow, liver, spleen, gastrointestinal tract, or other extranodal tissues, frequently including the skin. Presentation with bulky disease occurs 10% to 15% of the patients, which is less common than in aggressive B-cell lymphomas.

Constitutional symptoms, a poor performance status, and elevated LDH levels are reported in 40% to 60% of the cases, and approximately 50% to 70% of the patients have an intermediate-risk to high-risk international prognostic index (IPI).[12] Blood eosinophilia, anemia, and thrombocytopenia are present at the time of the diagnosis in a minority of patients. The occurrence of a hematophagocytic syndrome in some patients is often associated with a rapidly fatal course.[14]

The etiology of the disease, or more likely diseases, is unknown. In a minority of cases, associations with other clinical conditions have been reported. For example, patients with the lymphoproliferative variant of the hypereosinophilic syndrome, a condition associated with a clonal proliferation of IL-5 producing T cells, may secondarily develop a T-cell lymphoma most commonly reported, AITL, or PTCL, NOS.[15-20] The occurrence of cutaneous or systemic T-cell neoplasms in patients with chronic lymphocytic leukemia (CLL) has been documented in several case reports and case series; the majority consisted of PTCL, NOS, often with a cytotoxic phenotype, or anaplastic large cell lymphoma (ALCL), anaplastic lymphoma kinase

(ALK) positive or ALK negative.[21] The interval between the diagnoses of CLL and PCTL in these patients was on average 5 years.[22-24] Mechanistically, lymphomagenesis has been linked to the accumulation of oligoclonal or monoclonal T-cell populations with abnormal phenotypes or disrupted functional properties commonly observed in CLL patients.[21,22]

Immunocompromised patients in general have an increased risk of developing PTCL, which is more frequently extranodal and develops at a younger age compared with the general population.[25] Among the very rare HIV-associated lymphomas of T-cell phenotype, which tend to occur predominantly in male individuals under combined antiretroviral therapy, PTCL, NOS is the most common type, and a subset of cases are EBV-positive, now classified as primary nodal EBV-positive T/NK-cell lymphoma.[26] PTCL, NOS is also the most frequent type of posttransplant lymphoproliferative disorders of T-cell lineage, the latter representing only a small proportion of all PTCLs, and being EBV negative in less than half of the cases.[27] PTCL, NOS in the posttransplant setting tends to occur late after transplantation and their molecular and genomic alterations appear similar to those found in PTCL, NOS in immunocompetent hosts, suggesting common mechanisms of lymphoma development.[28] The occurrence of nodal T-cell lymphomas has been reported in patients with rheumatoid arthritis under treatment with methotrexate; among the 28 patients described by Satou et al., who were elderly individuals (median 70 years) under methotrexate for 0.5 to 21 years, there were 19 AITL, 8 PTCL, NOS, and 1 case of EBV-positive CD8-positive nodal T-cell lymphoma, consistent of primary nodal EBV-positive T/NK-cell lymphoma following current terminology.[29]

Morphology

PTCL, NOS encompasses a broad morphologic spectrum. Most commonly, lymph nodes are involved in a diffuse fashion (**Fig. 34-1A**). High endothelial venules are usually increased, and arborizing vessels are often abundant (**Fig. 34-1B**). However, at variance with AITL, an open peripheral sinus and stromal expansion of follicular dendritic cells are not seen (**Fig. 34-1C–D**). Some cases may present with an interfollicular or paracortical infiltrate sparing persistent follicles, a pattern formerly referred to as "T-zone variant" (**Fig. 34-1E–F**).[30] However, it has turned out that many cases with a T-zone pattern of involvement correspond to CD4-positive PTCL with a TFH phenotype and are now classified as TFH lymphoma, NOS. Hence, while the term may be used in the histologic description, it is nonspecific and no longer designates a variant of PTCL, NOS. Likewise, follicular PTCL characterized by a nodular growth in association with follicular dendritic cells and variable amounts of small B cells, resembling follicular lymphoma or progressively transformed germinal centers, originally considered as a variant of PTCL, NOS,[31] was later identified as a rare form of nodal TFH-derived lymphoma, and is now classified as TFH lymphoma, follicular type.[1,32,33]

In PTCL, NOS, the neoplastic cells are typically pleomorphic, with most cases containing a mixed population of smaller and larger cells. Many cases consist predominantly of medium-sized or large-sized cells with round, oval, or irregular nuclei containing prominent nucleoli and many mitotic figures (**Fig. 34-2A**).[4,30,34] Less common, small pleomorphic T-cell lymphomas have a predominance of atypical small cells with irregular nuclei (**Fig. 34-2B**).[35] Irregularity of nuclear contours may be a helpful hint to suspect the neoplastic nature

of infiltrates composed predominantly of small cells. Some cases have atypical cells with clear cytoplasm and irregular or round nuclei. Some tumors contain scattered large, atypical cells resembling Hodgkin or Reed-Sternberg cells (HRS-like cells), which may correspond to the most atypical component of the neoplastic population, or bystander B-cell blasts. With relapse, the tumors tend to retain similar morphologic features and pattern of nodal involvement, or may show histologic progression with increased numbers of large cells.[36] Morphologic grading is not recommended for clinical purposes, but tumors with a predominance of large cells have been found to have a worse outcome.[12]

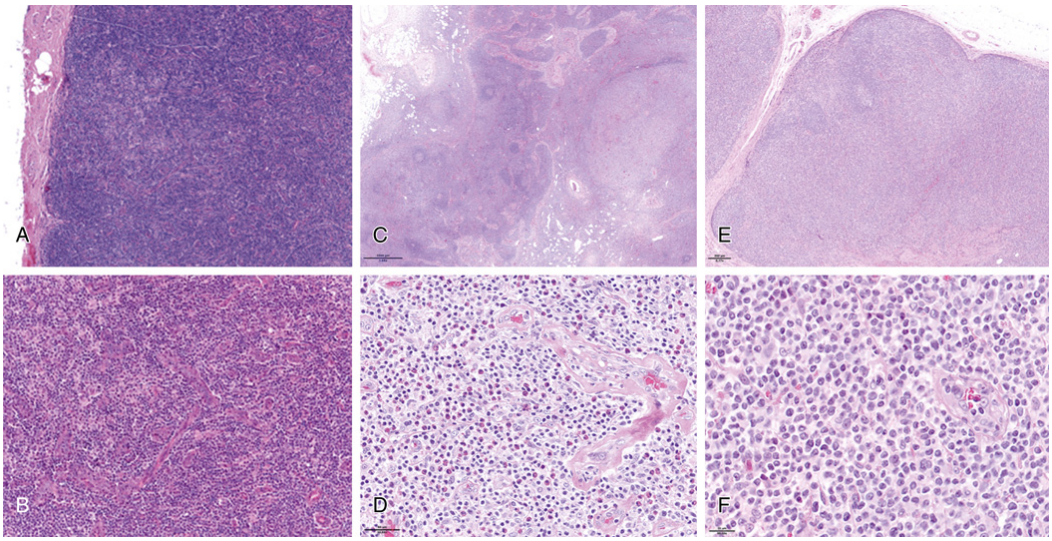

FIGURE 34-1 Patterns of peripheral T-cell lymphoma, not otherwise specified.A–B, Peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS) with diffuse nodal involvement, and prominent venules. **C–D,** PTCL, NOS extending into the perinodal tissues, without preservation of the sinus; in this case that arose in a patient with a history of lymphocytic variant of hypereosinophilic syndrome, the small-to-medium-sized atypical cells were admixed with numerous eosinophils. **E–F,** PTCL, NOS showing extensive lymph node involvement preserving reactive follicles, and composed of rather monotonous medium-sized atypical cells.

Many cases have a polymorphous cellular composition, with an admixture of reactive cells, including small lymphocytes, eosinophils, histiocytes, B cells, and plasma cells. Any of these bystander cell components can be prominent, obscure the neoplastic cells and represent a compounding factor to establishing a correct diagnosis.

The rare cases with a prominent infiltrate of epithelioid histiocytes, referred to as lymphoepithelioid lymphoma (Lennert lymphoma) (**Fig. 34-2C–D**), may constitute a distinctive subtype.

Immunophenotype

The common leukocyte antigen (CD45) and T-cell–associated antigens (CD3, CD2, CD5, CD7, CD43) are positive, but aberrant T-cell phenotypes with a lack of one or several of these markers (most commonly CD5 or CD7) are typically encountered (**Fig. 34-3**).[37,38] Most cases are single positive CD4 positive, or less often CD8-positive T cells, but a significant proportion of tumors are double-negative, or more rarely positive for both antigens.[37-39] Whether the expression of CD4 or CD8 is associated with any prognostic effect is unclear, but there have been suggestions that CD4-positive cases tend to be associated with a better outcome, while conversely a double-negative immunophenotype might be associated with an unfavorable prognosis.[38,39] In >85% of cases the neoplastic cells express the alpha/beta T-cell receptor (TCRβF1+), and a minority cases are either of gamma/delta derivation (positive for TCR gamma or TCR delta), or negative for both (TCR silent).[38,40,41] Loss of BCL2 by the neoplastic T cells, which is observed in 45% to 60% of the cases, can be a useful marker indicative of T-cell malignancy, also applicable to other types of mature T-cell neoplasms.[42,43]

An aberrant immunophenotype is usually interpreted as the phenotypic expression of a neoplastic genotype and represents the main tool available on routine tissue sections to infer clonality/malignancy in T-cell lymphoproliferations. Besides, there are direct means of assessing clonality of T-cell populations by flow cytometry[44] using V-beta analysis with specific antibodies directed to

the 24 V-beta families, with a clonal population being defined by expressing one or none of the V-beta families, or by assessment of TRBC1 (T-cell receptor constant beta chain-1) expression. The latter method, recently developed, is based on a single antibody recognizing TRBC1, which is expressed mutually exclusive to TRBC2, a clonal population being defined as positive or negative for TRBC1.[45] This simple assay is unfortunately not applicable for immunohistochemistry on routinely processed tissues.

A subset of PTCL, NOS, ranging from 15% to 30% to 40% of the cases in various series, express one or several cytotoxic granule-associated molecules (T-cell intracellular antigen [TIA], granzyme B, or perforin) indicative of a resting or more commonly activated cytotoxic immunophenotype (**Fig. 34-4**).[38,39,46]

By definition, the neoplastic cells in PTCL, NOS must lack a TFH immunophenotype. The latter applies to CD4-positive cells expressing two or more key markers of TFH cells. The recommended panel includes five antibodies (BCL6, CD10, CXCL13, PD1, ICOS/CD278),[1,33] but other markers of TFH cells can be taken in consideration as well in this context, for example CD57, CD200, CXCR5, or SAP. Importantly, none of these markers is totally specific for TFH lineage differentiation, and each might be occasionally be expressed in PTCL, NOS, usually in a nonhomogeneous fashion and with weaker or heterogeneous intensity than expected in TFH lymphomas (see the cases illustrated in Figs. **34-7** and **34-9**).[47] Regarding nuclear markers, PTCL, NOS is usually positive for Lymphoid Enhancer Binding Factor 1 (LEF1)[48] and negative for BCL6, FOXP3, and TCL1 transcription factors, which are, respectively, critical for TFH differentiation and function, related to regulatory T cells, and overexpressed in T-cell prolymphocytic leukemia.[49,50] A few

cases of FOXP3-positive PTCL, NOS have been described in patients negative for HTLV1 infection; these cases were composed of large cells, some with EBV reactivation in bystander cells, and the clinical course was aggressive.[51] PTCL, NOS neoplastic cells variably express TBX21 (t-bet), and GATA3, which, in normal lymphoid cells, reflects Th1 and Th2 pathways of differentiation.[52]

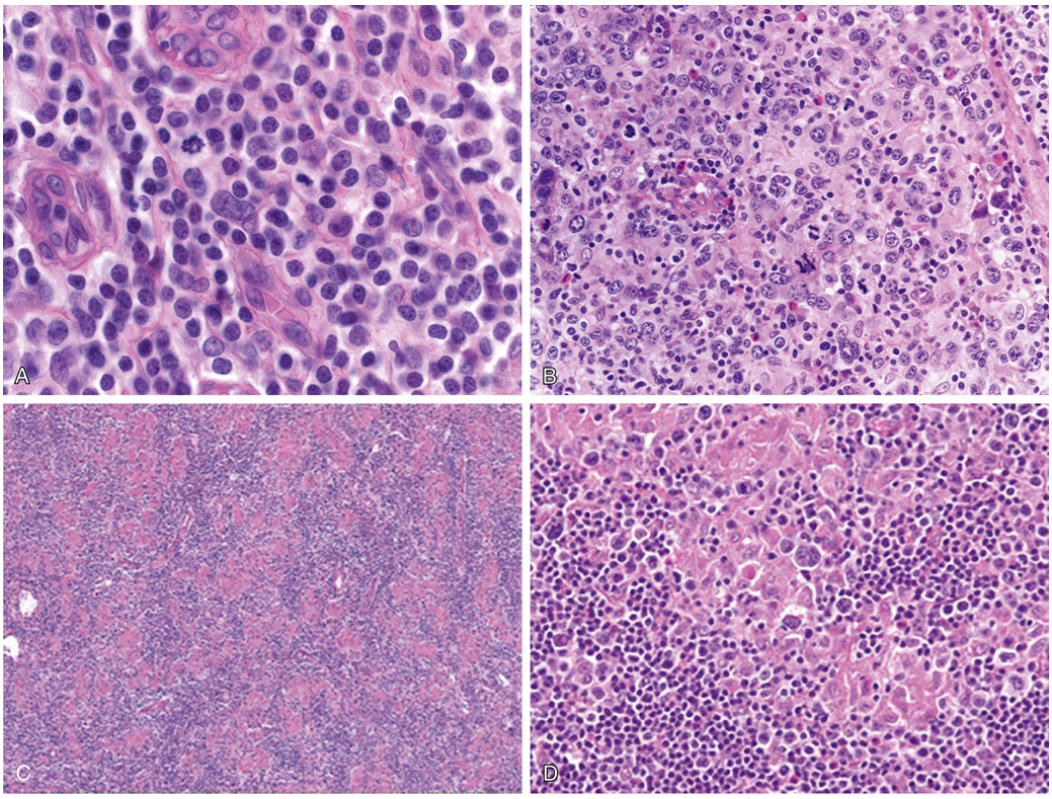

FIGURE 34-2 Morphologic spectrum of peripheral T-cell lymphoma, not otherwise specified.A, Peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS) composed of pleomorphic medium-to-large-sized cells and occasional Reed-Sternberg (RS)–like cells. **B,** PTCL, NOS composed predominantly of small cells, with scattered large, transformed cells; note the presence of mitotic figures and nuclear irregularities. **C–D,** Lymphoepithelioid variant of PTCL, NOS (Lennert lymphoma) comprising prominent epithelioid histiocytes, imparting a vaguely granulomatous appearance; most

lymphoma cells are small, and a few are larger, sometimes with RS-like morphology.

CD20 and other B-cell markers usually highlight a small number of reactive B cells. In addition, in rare cases of PTCL, NOS (5% or less) the neoplastic cells co-express CD20 (**Fig. 34-4**). The intensity of CD20 expression may be dimmer than that of normal B cells, and its distribution may be restricted to a subset of the neoplastic population that is otherwise positive for pan–T-cell antigen(s). It is unclear whether CD20 expression in PTCL, NOS reflects the derivation from a subset of $CD20^{dim}$ T cells that has undergone transformation, or is a marker of activation and proliferation of neoplastic T cells. There is no correlation with morphologic features and the anatomic sites of disease involvement are variable. CD20-positive PTCL, NOS occurs predominantly in elderly males and pursues an aggressive course in many cases. Expression of other B-cell markers (CD19, CD79a, PAX5) has been documented in rare cases of PTCL, NOS, but co-expression of several of them seems exceptional.[53-56]

The activation marker CD30 is often detected in occasional tumor cells, and can be more extensively expressed.[48,57,58] In a study of 141 PTCL, NOS, we found that 58% of the cases had in at least 5% CD30-positive tumor cells, and more than 20% of the cases were extensively positive (in 50% or more of the tumor cells).[58] Staining extent and intensity tend to correlate, and are higher in cases with large cell morphology. Strong CD30 expression by a majority of the tumor cells is seen occasionally; in these cases, ALK expression must be excluded, and the differential diagnosis consideration is with ALK-negative ALCL. Co-expression of CD30 and CD15 has been reported in some PTCL, NOS, including a subset of cases containing RS–like cells

mimicking classic Hodgkin lymphoma (**Fig. 34-5**), and the expression of CD15 in PTCL, NOS has been reported as an indicator of a poorer prognosis.[38,59] More recently, Fitzpatrick et al. described *JAK2* rearrangements in six cases of CD30-positive nodal T-cell lymphomas with anaplastic morphology and multinucleated cells resembling RS cells in a polymorphous background.[60] Three cases were classified as CD30-positive PTCL, NOS and three as ALK-negative ALCLs, and 4/5 cases were CD15 positive. The presence of *JAK2* fusions defines another genetic variation of ALK-negative ALCL in that context; nevertheless, additional studies are required to confirm these findings.

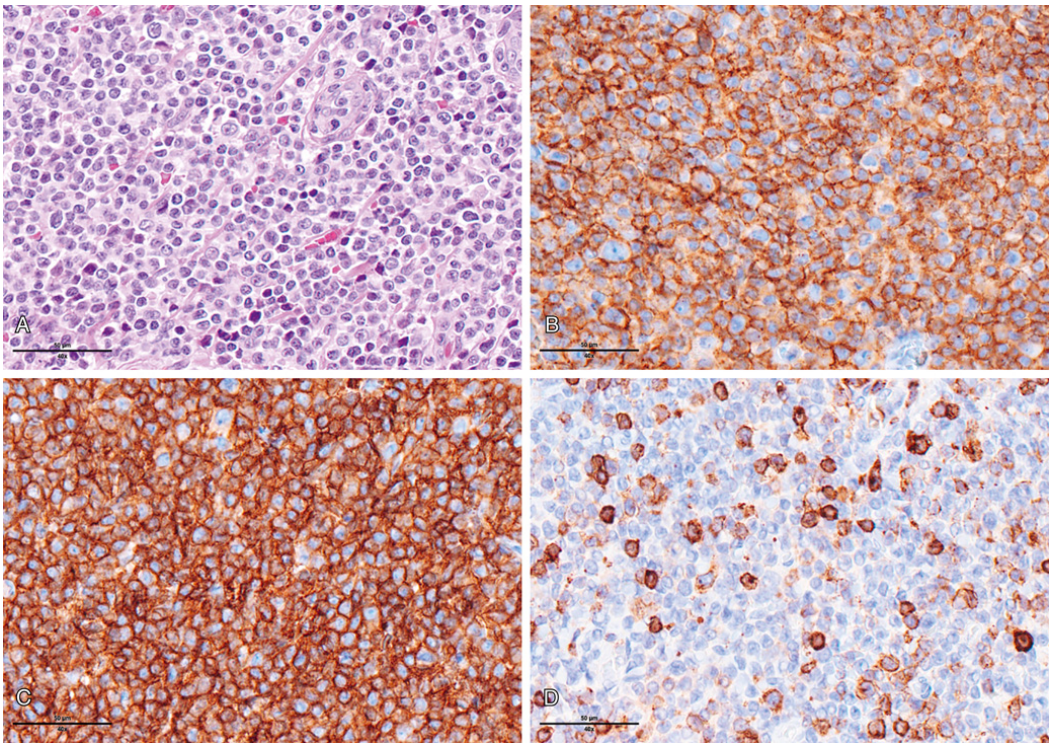

FIGURE 34-3 Defective T-cell antigen expression in peripheral T-cell lymphoma, not otherwise specified.A, This tumor comprises medium-sized and occasional larger cells. The neoplastic cells are positive for CD4 **(B),** positive for CD5 **(C),** and negative for CD7 **(D).**

Besides its diagnostic value, CD30 immunohistochemistry may also inform therapeutic decisions given the availability of CD30 antibody-drug conjugates, which are approved for the treatment of PTCLs. For that purpose, it is recommended to report estimated percent positive expression in tumor cells (or total cells where applicable) and record descriptively if nontumor cells are positive.[61] Any degree of CD30 expression should be reported, and despite the fact that CD30-directed treatment with brentuximab vedotin is significantly more effective against strongly CD30-positive PTCL, there have been

responses observed in patients with very low or undetectable CD30 expression, and therefore, no threshold for positive versus negative expression is established.[62] The interleukin receptor (CD25), another potential target for immunotherapy in PTCL, acted on by a recombinant diphtheria toxin-IL-2 fusion protein, is expressed at significant levels in roughly 40% of PTCL, NOS.[42]

The Epstein-Barr virus (EBV) is detected in up to 50% of the cases, and this finding is correlated with a worse survival.[63,64] In most instances, only a small number of cells are positive by in situ hybridization and mainly represent bystander B cells, although in some cases it cannot be excluded that a fraction of the neoplastic cells may contain the virus.[63] In the rare instances where the majority of the tumor cells harbor EBV, these cases are now classified as a separate entity, namely primary nodal EBV-positive T/NK-cell lymphoma.

The presence of EBV-positive B-blasts or RS-like cells and the occurrence of EBV-negative clonal or monotypic plasma cell or B-cell proliferations with plasma cell differentiation, which are common in PTCLs of TFH origin, have been described less frequently in PTCL, NOS; however, some of these reports antedate the recognition of nodal PTCLs of TFH derivation, and it is uncertain whether they all represent true PTCL, NOS according to the current defining criteria.[65-67] The HRS, which are often EBV positive, may express reduced levels of B-cell antigens, are almost always CD30-positive and also often CD15-positive (at least focally) (**Fig. 34-6**).[68] EBV-positive HRS-like cells were found almost constantly in cases of methotrexate-associated PTCL.[29] The importance of the B-cell expansion is variable and may be extensive, ranging from isolated or small clusters of activated B cells to confluent sheets of transformed B cells that may

even partly obscure the neoplastic population.[65,66] In those instances, a secondary diagnosis of diffuse large B-cell lymphomas might be considered.

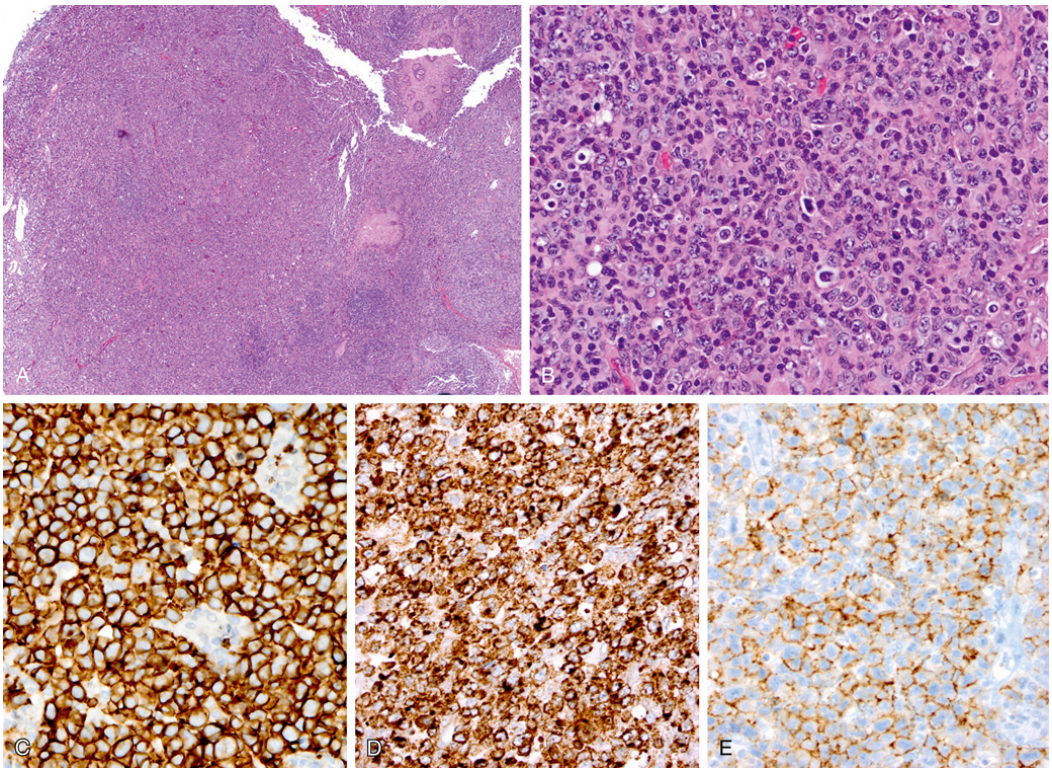

FIGURE 34-4 Peripheral T-cell lymphoma, not otherwise specified, CD20 positive.A, This case involved the tonsil as an interfollicular and diffuse infiltrate. **B,** The infiltrate was composed of medium-to-large-sized cells with multilobated forms, prominent nucleoli, and focal necrosis. The lymphoma cells are CD8 positive **(C),** show an activated cytotoxic phenotype (granzyme B positive) **(D),** and partially co-express CD20 **(E).** *Courtesy from Aliyah Sohani and Judith Ferry, Massachusetts General Hospital, Boston, MA.*

Genetic and Molecular Characteristics

Antigen Receptor Genes

Clonally rearranged TR genes can be demonstrated in most cases. Using the polymerase chain reaction (PCR)–based BIOMED-2 multiplex protocols, the clonality detection rate is >90% for each of both TRB or TRG targets, and reaches 100% when combining both strategies.[69] Simultaneous detection of a clonal or oligoclonal immunoglobulin (IG) gene rearrangement has been reported in up to one-third of the cases, usually but not always in correlation with the presence of EBV-positive cells or morphologic evidence of a B-cell expansion.[70] The limitations of TR gene clonality assay based on fragment analysis, which encompass low sensitivity and the risk of false-positive results, are overcome by more recent next-generation sequencing (NGS) amplicon-based assays using primer sets targeting various regions of the TRB or TRG genes, which allows more accurate assessment of clonality, with precise identification and quantification of distinct clonal sequences.[71]

Genetic Abnormalities

By conventional cytogenetics, clonal aberrations comprising a vast number of different numerical and structural alterations have been described.[72-74] Complex karyotypes have been reported to correlate with larger cell morphology[73] and with an inferior outcome.[75] Virtually all cases harbor genetic imbalances, with gains outnumbering losses. By CGH,[75-77] recurrent gains have been observed in chromosomes 7q,[78] 8q,[77] 17q and 22q, and recurrent losses in chromosomes 4q, 5q, 6q, 9p, 10q, 12q, and 13q. In their study, Zettl et al. identified a group of nodal cytotoxic CD5-positive PTCL, NOS, associated with deletions in chromosomes 5q, 10q, and 12q, and with a better prognosis.[76] For a few altered loci, correlation with deregulated gene expression has been demonstrated, and by this

approach a few genes of interest have been highlighted. For example, gains at 7q have been found to target cyclin-dependent kinase 6,[78] those at 8q involve the *MYC* locus,[77] losses at 9p21 associate with a reduced level of expression of two inhibitors of cyclin-dependent kinases, and gains at 7p22 correlate with increased levels of CARMA1, a factor involved in the activation of NF-κB.[79] A whole genome-sequencing study showed that *CDKN2A* and *PTEN* deletions are frequent (46% and 26% of the cases, respectively), and may co-occur, this event being specifically associated with PTCL, NOS and never observed in AITL.[80] *CDKN2A* deletions, which were found associated with shorter survival in that study, are recurrent in the GATA3 molecular subgroup of PTCL, NOS.[81]

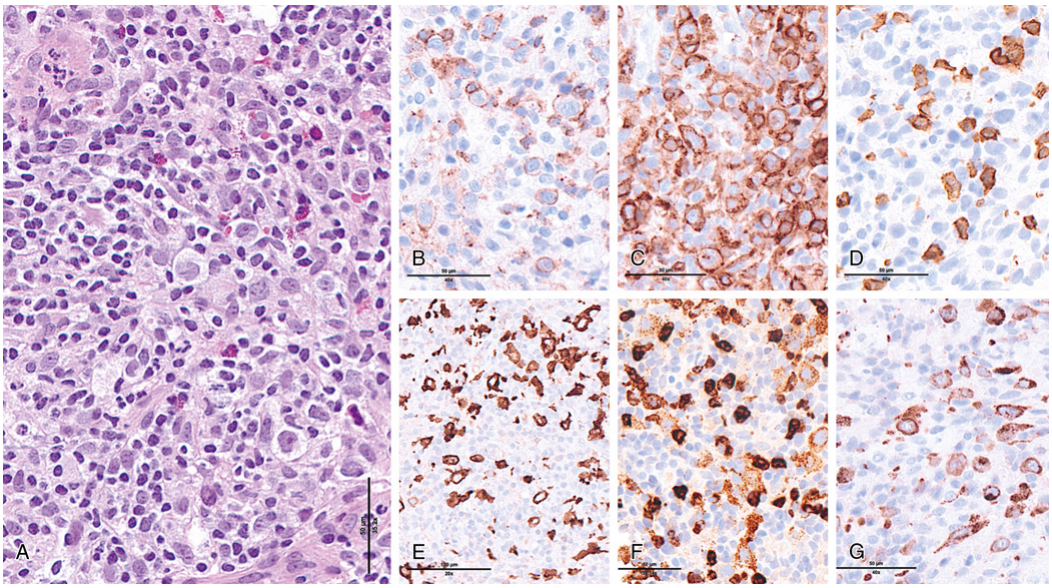

FIGURE 34-5 Peripheral T-cell lymphoma with co-expression of CD30 and CD15.A, This lymphoma comprises a pleomorphic population of smaller to larger cells including large, atypical cells with prominent nucleoli and abundant cytoplasm. **B,** The neoplastic cells show heterogeneous CD2 expression. They are positive for CD4 **(C)** and negative for CD8, which stains a few reactive cells in the microenvironment **(D).** CD30 is strongly positive in the larger cells **(E),** which are also CD15 positive **(F). G,** A cytotoxic phenotype is demonstrated by perforin expression.

Chromosomal breaks involving the TR gene loci (mostly the A/B TR locus at 14q11.2) have been reported in rare cases of PTCL, NOS, but the translocation partner(s) has been identified in only occasional cases.[75,82-84] The t(14;19)(q11;q13) translocation involves the poliovirus receptor-related 2 gene *(PVRL2)* and induces overexpression of both *PVRL2* and *BCL3* mRNAs.[85,86] The multiple

myeloma oncogene-1/interferon regulatory factor-4 *(IRF4)* is the gene partner in chromosomal translocations involving the TRA gene in the t(6;14)(p25;q11.2) translocation described in rare cases of clinically aggressive cytotoxic PTCL, NOS involving the bone marrow and skin or spleen (**Fig. 34-7**).[87,88]

High-throughput sequencing studies have discovered several recurrent fusion transcripts. Overall, their individual prevalence is low, and they are not specific for PTCL, NOS, as they also occur in other T-cell lymphoma entities, in particular ALK-negative ALCL or TFH lymphomas.[89-92] *TP63* rearrangements with *TBL1XR1* or other partner genes, encoding fusion proteins homologous to ΔNp63, a dominant-negative p63 isoform that inhibits the p53 pathway, are detected in about 5% of PTCL, NOS. *TP63* rearrangements are associated with an aggressive clinical course and bad outcome.[93,94] Fusions involving *VAV1 (VAV1*::*MYOF1, VAV1*::*THAP4, VAV1*::*S100A7)* result in increased activation of VAV1 effector pathways and the oncogenic properties of *VAV1*::*MYOF1* were demonstrated in mice *in vivo*.[95,96] The *FYN*::*TRAF3IP2* fusion found in PTCL, NOS and TFH lymphomas activates the NF-κB pathway.[92,97] Fusions involving *CD28* (*CD28*::*CTLA4* and *CD28*::*ICOS*) occur in PTCL, NOS but are more common in TFH lymphomas and adult T-cell leukemia/lymphoma.[90]

The mutational landscape of PTCL, NOS includes recurrent mutations in epigenetic modifiers, most often *TET2* or *DNMT3A,*[98] less commonly *SMARCA4* or *KMT2D,* in genes related to the TCR signaling pathway, notably activating mutations in *PLCG1, CD28* and *VAV1*.[89,99-101] Mutations in *RHOA* and *IDH2* recurrent in TFH lymphomas, especially of AITL type, are not detected in PTCL, NOS. Alterations in *TP53* (mutations or deletions, often biallelic) are

detected in 40% of the cases, and portend an adverse prognostic significance.[81,102] One study found that alterations in *TP53* or *CDKN2A* delineate a group of PTCL, NOS characterized by marked genomic instability, mutations in genes related to immune surveillance and immune evasion *(HLA-A, HLA-B, CIITA, CD58, CD274)*, mutations in transcriptional and posttranscriptional regulators, and a worse outcome.[102]

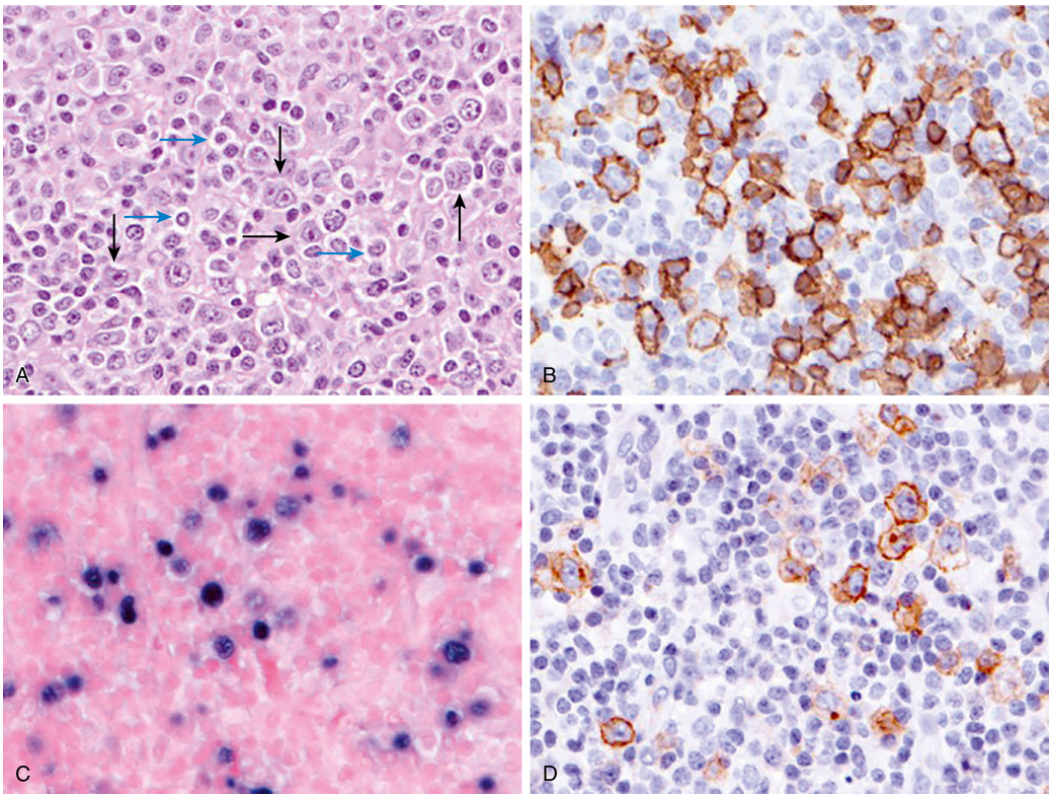

FIGURE 34-6 Epstein-Barr virus–positive B-cell blasts in peripheral T-cell lymphoma, not otherwise specified.A, Peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS) comprising large atypical blastic cells, sometimes with prominent nucleoli, and sometimes binucleate *(black arrows)*; the neoplastic component is represented by medium-sized lymphoid cells with clear cytoplasm *(blue arrows)*. **B,** CD20 stains the large blastic cells and a few smaller cells. **C,** The B-cell blasts are positive for EBV as shown here by in situ hybridization. **D,** They are positive for CD30.

Variants and Subgroups

Lymphoepithelioid Variant of PTCL, NOS

The lymphoepithelioid variant of PTCL, NOS, originally described by Professor Karl Lennert in 1952 as a variant of Hodgkin disease, also known by the eponymous *Lennert's lymphoma* or *Lennert lymphoma*, is characterized by a prominent reactive infiltrate of epithelioid histiocytes, consisting mainly of mononucleate cells and distributed singly or more typically in small clusters (**Fig. 34-2C–D**).[103] The histiocyte cells may be so abundant to mimic a granulomatous reaction and obscure the neoplastic cells, which are small atypical T cells with slight nuclear irregularities.[30] In addition, RS-like cells, eosinophils, and plasma cells are also commonly seen.[104] The pattern of Lennert lymphoma is usually diffuse but may be interfollicular. Lennert lymphoma is overall rare, accounting for less than 10% of PTCL, NOS in historical series.[12] In addition, in recent years, reassessment of Lennert's own files and other small cohorts of such cases has revealed that many cases of PTCL with a lymphoepithelioid pattern in fact correspond to histiocyte-rich TFH lymphomas of the angioimmunoblastic type or NOS.[105-107] Thus, only a fraction (actually a minority) of lymphoepithelioid T-cell lymphomas remain categorized as PTCL, NOS according to current criteria. These lymphomas tend to mostly involve lymph nodes, are derived from CD8-positive cells in the majority of cases, but may also be CD4 positive, double positive, or double negative, and are characterized by a nonactivated cytotoxic immunophenotype.[39,108,109] Lymphoepithelioid PTCL has been found to be associated with an overall better prognosis than usual PTCL, NOS,[12] and in comparison to patients with lymphoepithelioid lymphoma of TFH derivation, those with lymphoepithelioid PTCL, NOS were found to have a better outcome.[107,109]

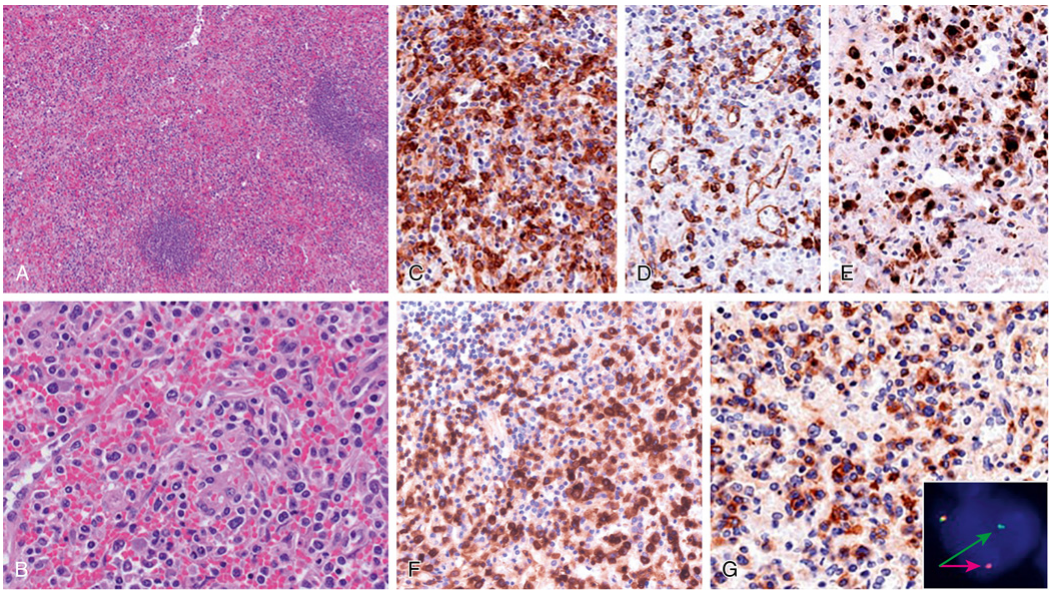

FIGURE 34-7 Peripheral T-cell lymphoma, not otherwise specified, with t(6;14)(p25;q11.2).A, In this case presenting with splenomegaly, the lymphoma cells diffusely infiltrate the red pulp and colonize the outer layers of the white pulp. **B,** The lymphoma cells are large and pleomorphic. **C,** They express CD4. **D,** A subset are CD8 positive. **E,** They are positive for granzyme B. **F,** They express the alpha/beta TCR isoform (BetaF1 immunostaining). **G,** The lymphoma cells are also positive for PD1 despite being clearly cytotoxic, emphasizing that PD1 expression alone is not specific of a T-cell follicular helper (TFH) immunophenotype. *Inset:* Break-apart fluorescence in situ hybridization (FISH) assay with probes spanning the *IRF4* locus at 6p25, demonstrating one red, one green, and one yellow

signal in the large nuclei of the lymphoma cells, indicative of an *IRF4* rearrangement.

Cytotoxic Molecule–Positive PTCL, NOS

Cytotoxic molecule–positive PTCL, NOS, is defined by the expression of one to several cytotoxic granule–associated antigens. Those most routinely tested are T-cell intracellular antigen-1 (TIA-1), which is expressed by both resting and activated cytotoxic T cells, and perforin and granzyme B, considered to be expressed upon activation, and is by definition EBV–negative. Nodal cytotoxic PTCLs composed of EBV-positive neoplastic cells are now classified as a separate entity, namely primary nodal EBV-positive T/NK-cell lymphoma, discussed below.[1,33] Apart from the lymphoepithelioid variant of PTCL, NOS, a subset of PTCL, NOS, estimated to represent between 15% and up to 30% of the cases in different series, have cytotoxic features (**Fig. 34-8**).[38,39,46,108,110] There is no established cut-off to define the cytotoxic marker positivity, but we recommend positivity in the majority of the neoplastic cells. In most instances an activated cytotoxic phenotype is demonstrated, but some cases may be positive for TIA-1 only, and others may express granzyme B or perforin in the absence of TIA-1. Most case series of cytotoxic PTCL, NOS have been reported from Asia, often admixed with EBV-positive PTCLs. A large European cohort of 45 EBV-negative nodal cytotoxic PTCLs was recently published.[101] In that series, the disease affected predominantly males at a median age of 60 years, primary nodal presentation was associated with extranodal involvement in the majority of cases, and an association with a previous history of B-cell lymphoma, solid cancer, or underlying immune disorder was noted in

one-fifth of the cases. Patients presented with clinical and biological parameters indicative of an aggressive disease and the median survival was 13 months. Comparison with noncytotoxic PTCL, NOS in another study indicates a lower overall survival for cytotoxic PTCL, NOS.[46] Accordingly, a molecular subgroup of PTCL, NOS defined by a cytotoxic signature was also found associated with a poorer survival.[111] Morphology of the tumors is variable, with predominantly medium-to-large-sized neoplastic cells and more or less abundant microenvironment. The neoplastic cells usually express CD2 and CD3, and frequently show partial or complete loss of CD5 or CD7. They are most commonly CD8+ or CD4−CD8−, less commonly CD4+ or CD4+ CD8+, and in most cases TCRβF1+ or TCR-silent, rarely TCR-γδ+.[39,46,101] One study from Japan found that a subset of cases with a CD5+ TCRαβ+ phenotype had a more indolent behavior.[112] CD30 co-expression is frequent and CD56 is expressed in rare cases, more commonly extranodal. Virtually all cases express Th1-associated markers TBX21 or CXCR3. Cytotoxic PTCL, NOS harbors frequent mutations in epigenetic modifiers, notably in *TET2* and *DNMT3A,* recurrent alterations affecting the T-cell receptor and JAK/STAT signaling pathways, including fusions involving *VAV1* and *CD28,* and *TP53* mutations in 18% of the cases.[101]

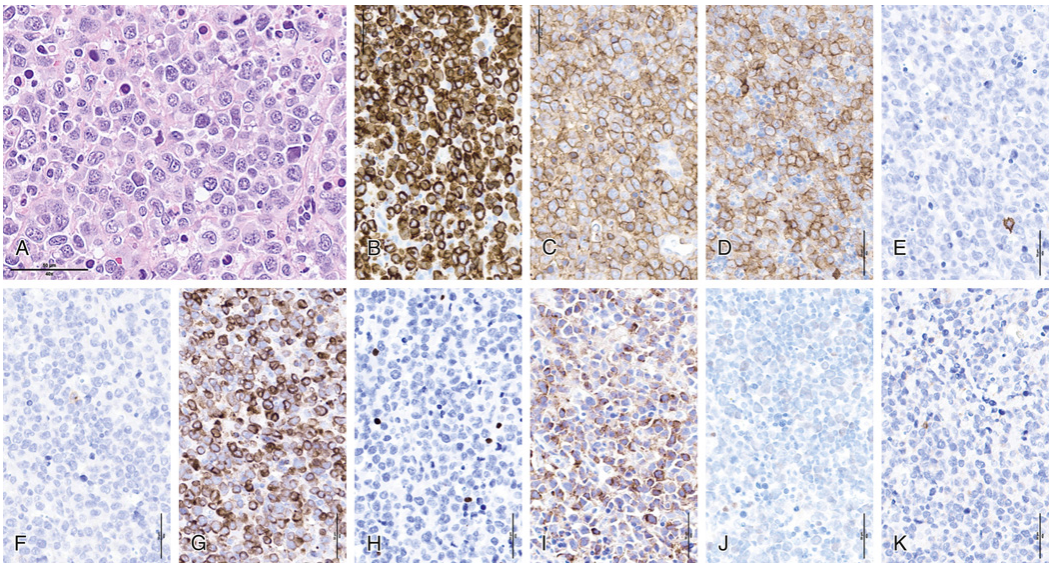

FIGURE 34-8 Cytotoxic TBX21-peripheral T-cell lymphoma, not otherwise specified.A, This nodal lymphoma is composed of large cells which are: $CD3^+$ **(B),** $CD4^+$ **(C),** $CD5^+$ **(D),** $CD8^-$ **(E),** $CD30^-$ **(F),** and strongly positive for perforin **(G). H,** TBX21 stained a few reactive cells and was negative in the neoplastic cells, which were otherwise positive for the other Th1-associated marker CXCR3 **(I),** and negative for both Th2-associated markers GATA3 and CCR4 (**J** and **K**).

Cell-of-Origin Subgroups

Earlier studies had suggested that subclasses of PTCL, NOS might be delineated by their immunologic profile according to the expression markers associated with Th1 (CXCR3, CCR5, CD134/OX40, CD69 T-bet) or Th2 [CCR4, CXCR4, ST2(L)] differentiation (**Table 34-1**).[113-117] Cases with expression of CXCR3, CCR5, or ST2(L) were reported to

have a more favorable prognosis than those negative for these markers,[116,117] and nonoverlapping subgroups of PTCL, NOS defined by the expression of CCR4, CCR3, or CXCR3 had significantly different outcomes.[117] These classifiers have not been widely applied because of technical difficulty in assessing these markers, which often requires fresh frozen tissue.

By transcriptome profiling, Iqbal et al. have identified two molecular subgroups of PTCL, NOS—PTCL-TBX21 and PTCL-GATA3—based on the similarities of their signatures to those regulated by the transcription factors TBX21 and GATA3, which are master regulators of TH2 and TH1 differentiation pathways, respectively.[111] Hence, the TBX21 subgroup shows high expression of TBX21 and its target genes *(CCL3, CXCR3, EOMES, IFNG, ILR2B)* and enrichment of the NF-κB pathway. Conversely, the GATA3 subgroup is characterized by high expression of GATA3 and its target genes *(CCR4, CXCR7, IL18RA)*, high MYC, and proliferation signatures.[111] Histologically, PTCL-TBX21 tends to be polymorphic with a background of reactive inflammatory cells, including cases of Lennert lymphoma, while PTCL-GATA3 tends to lack a prominent inflammatory microenvironment and consists of sheets of medium-sized tumor cells with abundant clear cytoplasm or clusters or sheets of large tumor cells (**Fig. 34-9**).[52] Further, GATA3-positive PTCL, NOS and cases with cytotoxic phenotype (clustered within the TBX21 subgroup) were found to have a worse outcome than noncytotoxic TBX21-positive tumors.[111,118,119] In addition, subsequent studies showed distinctive genetic features between the subgroups. PTCL-TBX21 has fewer copy number aberrations and a higher frequency of epigenetic-modifying gene mutations, especially those involved in DNA methylation (*TET1, TET3,* and *DNMT3A*). PTCL-GATA3 has greater genomic complexity;

frequent losses of *TP53, PTEN, RB1, CDKN2A/B,* and *PRDM1;* gains of *STAT3* and *MYC;* and recurrent mutations of *TP53* and *PRDM1,*[81] probably explaining their worse prognosis. An immunohistochemical algorithm has been developed to distinguish these two groups originally defined by gene-expression profiling–based methods. The algorithm uses four antibodies: TBX21, CXCR3 (a TBX21 transcriptional target), GATA3, and CCR4 (a GATA3 transcriptional target), which are interpreted sequentially.[52] Positivity for TBX21 or CXCR3 in 20% or more of the neoplastic cells defines the TBX21 subgroup. Lymphomas negative or below the threshold for TBX21 markers are classified as GATA3 if they express GATA3 or CCR4 in 50% or more of the neoplastic cells. Other cases remain unclassified. More recently, a simplified transcriptomic assay based on quantification of 153 selected transcripts dedicated for the molecular diagnosis of the major PTCL entities including the two subtypes of PTCL, NOS, has been implemented on a digital gene-expression profiling platform and validated in routinely processed samples.[120] The identification of the TBX21 and GATA3 subgroups currently has no effect on frontline clinical management of the patients and currently is not yet required or recommended in standard diagnostic practice.

Table 34-1

Comparison of TBX21 and GATA3 Subgroups of Peripheral T-Cell Lymphoma, Not Otherwise Specified

Feature	TBX21	GATA3
Frequency	50%–60% of PTCL, NOS	30%–40% of PTCL, NOS
Defining signature	High expression of TBX21 and its target genes *(CCL3, CXCR3, EOMES, IFNG, ILR2B)*	High expression of GATA3 and its target genes *(CCR4, CXCR7, IL18RA)*
Pathology	Polymorphous Cytotoxic subset	Medium-to-large-sized tumor cells Little inflammatory environment
Immunohistochemistry	TBX21 positive or CXCR3 positive	TBX21 negative and

Feature	TBX21	GATA3
		CXCR3 negative, GATA3 positive or CCR4 positive
Pathways	Enrichment of the NF-κB pathway	High MYC and proliferation signatures
Genetics	Relatively lower genomic complexity, mutations in epigenetic modifiers frequent	Higher genomic complexity, recurrent *TP53* alterations, *CDKN2A* and *PTEN* deletions
Outcome	Better than GATA3 except for the subset of cytotoxic cases	Worse than TBX21

Extranodal Peripheral T-Cell Lymphoma, Not Otherwise Specified

Bone marrow involvement by PTCL, NOS is detected in 20% to 30% of the staging biopsies. It can be interstitial or diffuse, usually with hypercellularity and extensive replacement of the normal hematopoietic tissue, or focal, usually nonparatrabecular. Mirroring the lymph nodes, the bone marrow infiltrates are often pleomorphic and associated with prominent vascularity, increased reticulin fibrosis, and an admixed reactive inflammatory infiltrate.[121,122] Rarely the bone marrow may be the main presenting site of the disease (**Fig. 34-10**).[123,124] The few cases of primary bone marrow PTCL, NOS, some of which occurred in children, had an interstitial and diffuse infiltration pattern, with eosinophilia in some cases. The variably sized atypical tumor cells variably express CD4 and CD8, are EBV negative, and expression of cytotoxic granule–associated proteins and PD1 is documented in several cases.

Splenic infiltrates may be in the form of single or multiple discrete lesions, as a micronodular pattern, or as diffuse parenchymal involvement of the red and white pulps (**Fig. 34-7**). Localization to T-cell–dependent regions, such as the periarteriolar lymphoid sheath (PALS) or marginal zone, may be seen.[125] In the liver, there may be portal, lobular, or sinusoidal infiltrates.

The skin may be the first and main presenting site for PTCL, NOS, and conversely, cutaneous involvement is frequent in cases of systemic PTCL, NOS. While the WHO 5th ed. has created a new category for primary cutaneous PTCL, NOS, this entity does not exist in the 2022 ICC. So far, there are no available data to suggest that PTCL, NOS presenting in the skin should be recognized as a separate entity. In principle, PTCL, NOS may present in any extranodal site. The only exception is primary intestinal T-cell lymphoma, NOS, which is individualized from other PTCL, NOS because these cases presenting

primarily in the gastrointestinal tract are potentially related to other primary intestinal T-cell lymphomas. Cutaneous infiltrates in PTCL, NOS can be diffuse, nodular, or bandlike; angiocentricity and epidermotropism can be seen.[126]

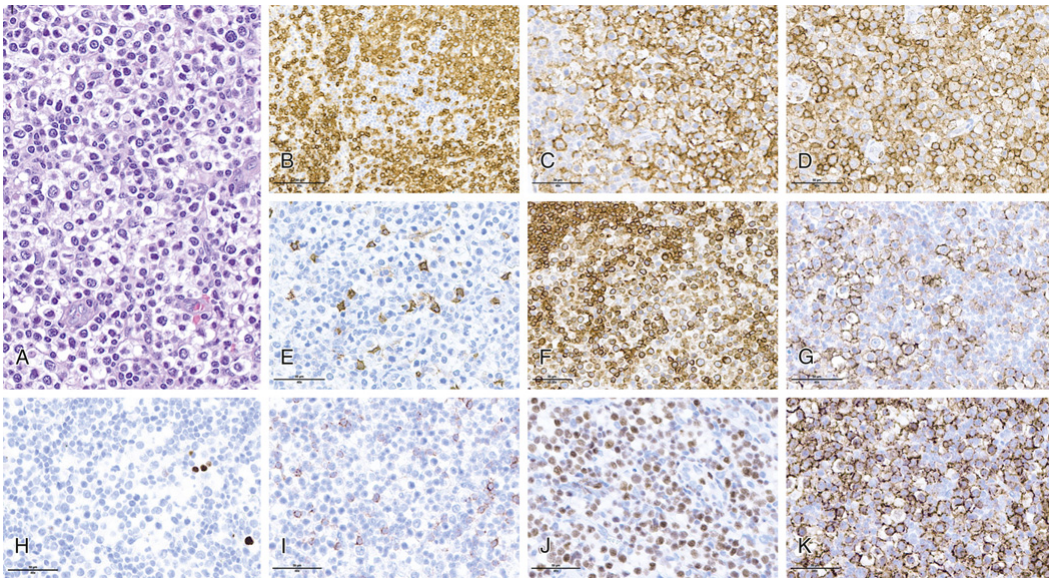

FIGURE 34-9 GATA3-peripheral T-cell lymphoma, not otherwise specified.A, This nodal lymphoma is composed of sheets and clusters of large cells with abundant clear cytoplasm. The neoplastic cells are CD3 positive **(B),** CD4 positive **(C),** CD5 positive **(D),** and CD8 negative **(E). F,** BCL2 is positive in the neoplastic cells with an intensity of staining weaker than in the reactive small lymphoid cells surrounding the aggregates of clear cells. **G,** The majority lymphoma cells are PD1 positive, but the other T-cell follicular helper (TFH) markers tested (BCL6, CD10, ICOS, and CXCL13) were not detected. The lymphoma cells are negative for TBX21 **(H)** and CXCR3 **(I),** and strongly positive for both GATA3 **(J)** and CCR4 **(K).**

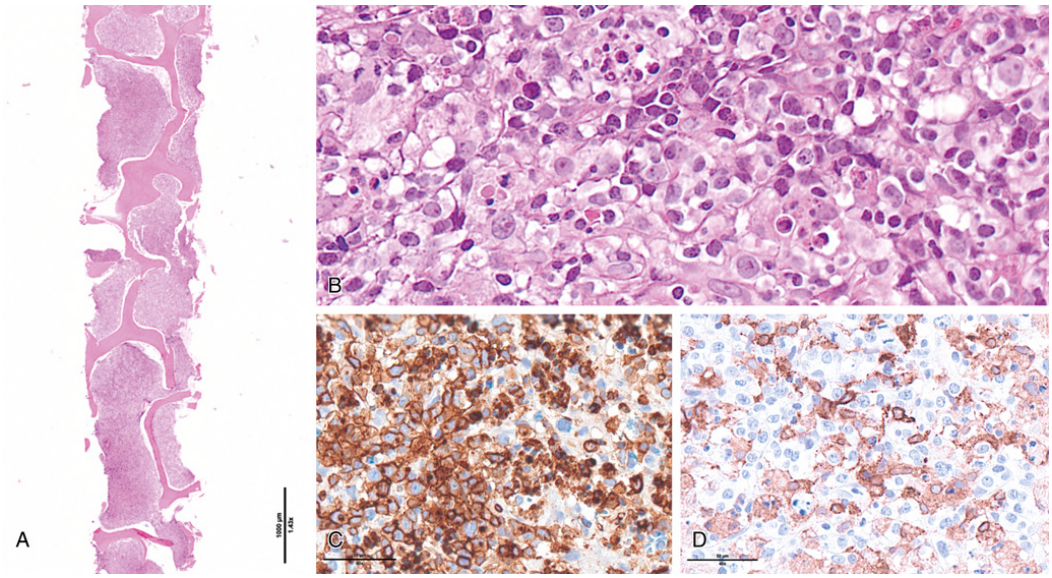

FIGURE 34-10 Primary bone marrow presentation of peripheral T-cell lymphoma, not otherwise specified.A, Low-power view of the trephine biopsy showing a diffusely, markedly hypercellular bone marrow. **B,** The hematopoietic tissue was replaced by a proliferation of large atypical lymphoid cells; there were numerous nuclear debris and accompanying macrophages. **C,** CD3 highlighted the neoplastic cells. **D,** CD163 stains many histiocytes and macrophages and shows hemophagocytosis.

Primary central nervous system PTCL, NOS is a rare condition accounting for <5% of primary central nervous system lymphomas.[127,128] It affects mostly elderly individuals although a few cases have been reported in younger adults, and manifests with neurologic deficits. The lesions are unique or multiple, usually supratentorial, less often cerebellar. The neoplastic cells are small-to-medium or medium-to-large, and necrosis and perivascular cuffing

are frequently observed. They express CD3, CD8, or CD4, often show aberrant T-cell antigen loss, and most of the cases have a cytotoxic phenotype. The few cases analyzed at the genomic level have shown heterogeneous mutations in various genes mutated in other T-cell lymphomas.

Prognosis and Predictive Features

PTCL, NOS is usually an aggressive disease, characterized by a poor response to therapy and frequent relapses. The 5-year overall survival of around 30% has not improved over the past years, and stratification of the patients according to the standard IPI is helpful for prognostication of outcome.[12,13,129] Italian investigators have suggested a novel prognostic index for T-cell lymphomas (PIT) based on four variables (age, performance status, LDH levels, and bone marrow involvement) that might be more appropriate than the IPI for PTCL, NOS patients.[130] Besides clinical factors, selected pathologic and biological prognostic markers are summarized in **Table 34-2**.

Primary Nodal Epstein-Barr Virus–Positive T/Natural Killer–Cell Lymphoma

Primary nodal EBV-positive T/NK-cell lymphoma is a new provisional entity in the 2022 ICC of lymphoid neoplasms.[3] It was originally reported and described as *EBV-positive nodal cytotoxic PTCL* in several publications from Asia,[131-134] and it was introduced in the 4th ed. revised WHO classification as a variant of PTCL, NOS (primary EBV-positive nodal peripheral T/NK-cell lymphoma).[2] In 2022, both the ICC and the WHO classification recognized it as a distinct entity, with features different from both PTCL, NOS, and from EBV-

associated extranodal NK/T-cell lymphoma, nasal type. The designation in the WHO 5th ed. is *EBV-positive nodal T- and NK-cell lymphoma*.[1] However, the word "primary" used in the ICC stresses one of the main criteria of the disease, namely that it should primarily involve lymph nodes, without nasal involvement.

Primary nodal EBV-positive T/NK-cell lymphoma is a rare disease with most series reported from Asia.[135] It is mostly diagnosed in elderly patients (median 60–65 years) or in a setting of HIV infection or other immunodeficiency conditions, and has a very poor prognosis with a median overall survival inferior to that of extranodal NK/T-cell lymphoma, nasal type (ENKTCL) and EBV-negative PTCL, NOS with a cytotoxic phenotype.[136] Patients tend to present with disseminated disease, generalized lymphadenopathy, frequent liver or spleen involvement, frequent B symptoms, and a high IPI. It is a systemic disease that lacks nasopharyngeal involvement. Such involvement should be investigated and excluded clinically. Involvement of other extranodal sites is variably reported in a small subset of patients.

Table 34-2

Pathologic Features of Peripheral T-Cell Lymphoma, Not Otherwise Specified With Suspected Prognostic Significance

Feature	More Favorable	Unfavorable
Morphology	Lymphoepithelioid variant	Predominance of large cells
Immunophenotype	CD4-positive phenotype Expression of CXCR3, CCR5, or ST2(L) TBX21/T-bet expression	CD8-positive or CD4–CD8-negative phenotype Expression of CCR4 GATA3 expression Cytotoxic phenotype Co-expression of CD20 Expression of p53
Epstein-Barr virus	Absent	Present
Cytogenetics		Complex karyotypes t(6;14) (p25;q11.2) translocation *TP63* rearrangements, *TP53*

Feature	More Favorable	Unfavorable
		mutations, *CDKN2A* alterations
Molecular	NF-κB pathway activation TBX21 signature	Proliferation signature GATA3 signature

The tumors are most commonly monomorphic and composed of large cells with centroblastoid morphology (**Fig. 34-11A**). Some cases are pleomorphic and may contain tumor cells with horseshoe-like or reniform nuclei. The tumors lack angiocentricity or angioinvasion, and necrosis is usually absent or limited. A subset of cases display massive necrosis or apoptosis, are accompanied by disseminated intravascular coagulation or hematophagocytic syndrome, and pursue a very aggressive or fulminant course.[108,137,138] The neoplastic cells express cytotoxic markers and are usually CD3-positive, CD8-positive, and CD56-negative (**Fig. 34-11B–E**). The cells might express strong CD30, a pitfall in the diagnosis if EBV-encoded RNA (EBER) in situ hybridization is not performed. Demonstration of EBV in most neoplastic cells is an essential diagnostic feature (**Fig. 34-11F**). Primary nodal EBV-positive T/NK-cell lymphoma is more often of T-cell rather than NK-cell origin. About 85% of cases carry clonally rearranged TR genes and express TCRαβ more commonly than TCRγδ.[135,139] True NK-cell derivation is inferred from silent TCR expression and lack of monoclonal TR gene rearrangements.

Primary EBV-positive nodal T/NK cell lymphoma is characterized by low genomic instability, upregulation of immune pathways within enhanced expression of proteins related to immune evasion such as the checkpoint protein PD-L1, and downregulation of EBV microRNAs. Few cases have been investigated by high-throughput sequencing and revealed recurrent mutations in *TET2, DNMT3A, STAT3, PIK3CD,* and *DDX3X*.[101,136]

Diagnostic Approach To Peripheral T-Cell Lymphoma, Not Otherwise Specified And Differential Diagnoses

The two components of PTCL, NOS diagnosis are, first, establishing a diagnosis of a neoplastic T-cell process, and second, excluding specific entities, including other nodal or extranodal entities and tissue involvement by leukemic T-cell neoplasms such as T-cell prolymphocytic leukemia. The diagnostic algorithm (**Fig. 34-12**) requires integration of clinical findings, including site of the disease, potential predisposing conditions like celiac disease, and HTLV1 serology, which should be systematically performed. The work-up characteristically integrates assessment of morphology, immunophenotype, and clonality studies. However, high-throughput sequencing, which is increasingly performed in the diagnostic setting, may provide additional information relevant not only to the diagnosis but potentially to inform therapeutic decisions.[140]

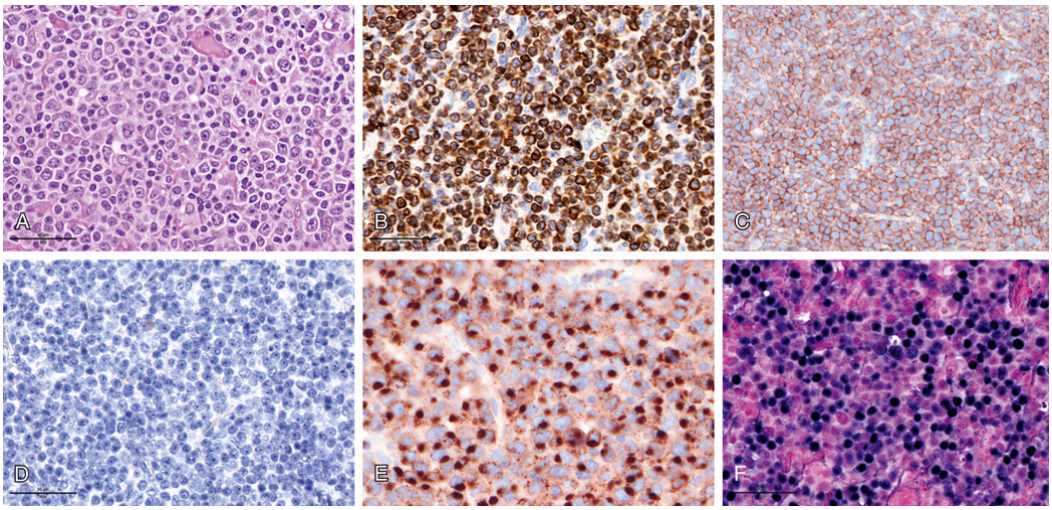

FIGURE 34-11 Primary nodal Epstein-Barr virus–positive T/natural killer–cell lymphoma.A, This lymphoma comprises diffuse sheets of large centroblastic-like monomorphic cells with no angiotropism or necrosis. The lymphoma cells are CD3 positive **(B),** CD8 positive **(C),** negative for CD56 **(D),** and homogeneously express granzyme B **(E). F,** Most cells are positive for Epstein-Barr virus (EBV), as demonstrated by in situ hybridization with EBV-encoded RNA probes.

Peripheral T-Cell Lymphoma, Not Otherwise Specified Versus Reactive Lymphoid Hyperplasia

Cases of PTCL, NOS consisting predominantly of small T cells may be confused with a reactive process. This relates particularly to cases showing a preserved architecture with residual, sometimes hyperplastic B-cell follicles, and interfollicular ("T-zone") involvement, and to lymphoepithelioid (Lennert) lymphomas. The

correct diagnosis can usually be established by careful morphologic and immunohistologic appraisal: a greater degree of architectural perturbation, extranodal extension of the lymphoproliferation, and cytologic atypia are typically found in cases of lymphoma, as is the demonstration of an aberrant T-cell immunophenotype, with loss of T-cell antigen expression. Assessment of clonality is in general desirable to formally confirm the diagnosis. The detection of somatic mutations using high-throughput sequencing may represent a useful adjunct to PCR-based assays for TR clonality testing to establish or, conversely, to exclude the presence of a clonal T-cell population.[141]

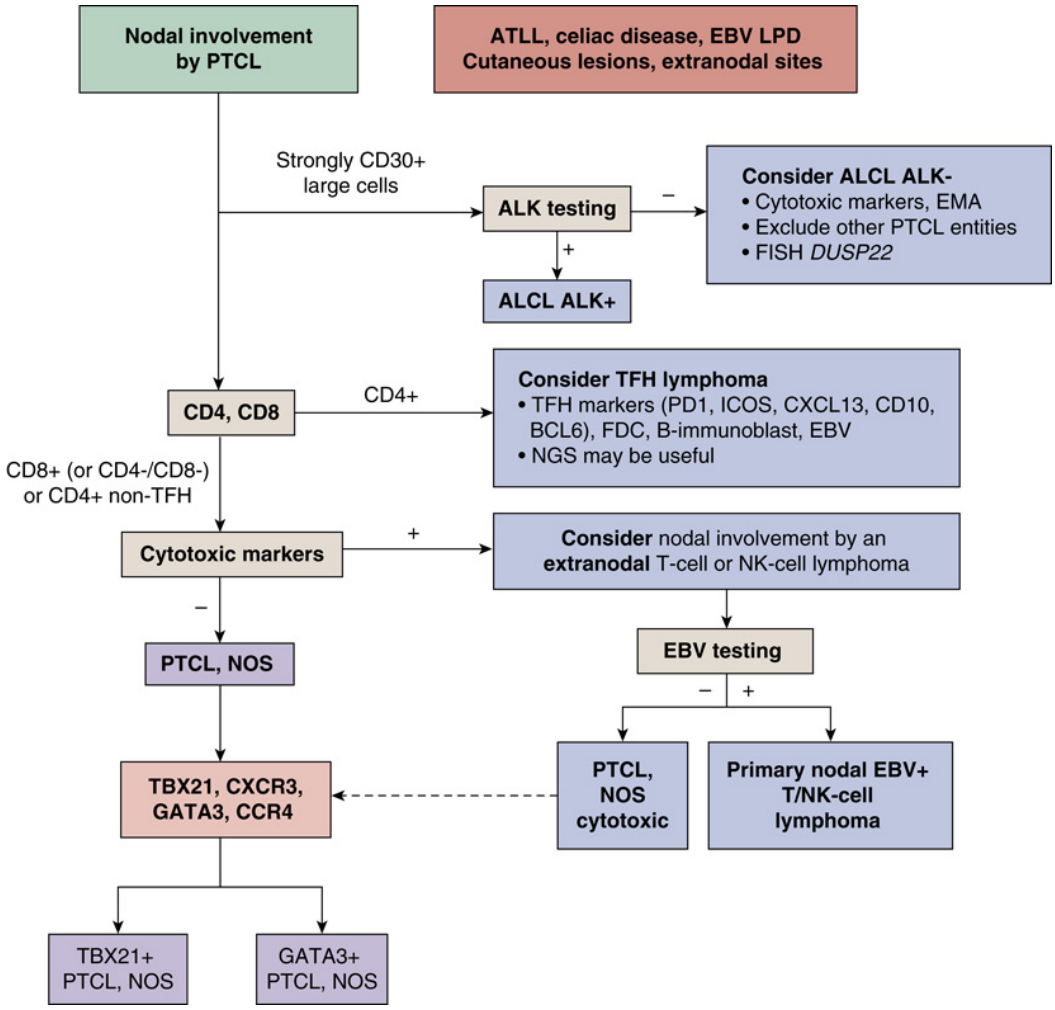

FIGURE 34-12 Diagnostic work-up of peripheral T-cell lymphoma, not otherwise specified. In cases of suspected nodal involvement by peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS), clinical history and presenting clinical characteristics are important to consider. Adult T-cell leukemia/lymphoma, which is morphologically diverse, is suspected in patients from an endemic area in the presence of a CD4-positive neoplasm with lack of CD7 expression and CD25 positivity and is confirmed by human T

lymphotropic virus 1 (HTLV1) infection. Distinction from anaplastic large cell lymphoma (ALCL) largely relies upon morphology and staining for CD30 and ALK. In CD4-positive PTCL, evaluation of T-cell follicular helper (TFH) markers, follicular dendritic cell meshworks, Epstein-Barr virus (EBV), and mutation analyses in some cases, are necessary to exclude TFH PTCL. Many of the cases where morphology raises a differential diagnosis between angioimmunoblastic T-cell lymphoma and PTCL, NOS, are now classified as TFH lymphomas. Cytotoxic marker expression raises the possibility of nodal involvement by an extranodal PTCL or natural killer (NK)/T-cell lymphoma, which requires integration of staging information. In the presence of an EBV-positive cytotoxic lymphoma, either of NK-cell or T-cell derivation, the possibility of secondary localization of extranodal NK/T-cell lymphoma, nasal type (ENKTCL) must be clinically excluded. At present, testing for TBX21 and GATA3 subgroups is not mandatory in routine diagnostic practice. *Adapted from Campo E, Jaffe ES, Cook JR, et al. The International Consensus Classification of Mature Lymphoid Neoplasms: a report from the Clinical Advisory Committee. Blood. 2022;140(11):1229-1253.*

In children, the autoimmune lymphoproliferative syndrome (ALPS), a primary immune disorder caused by mutations in the *FAS/FAS-L* leading to defective apoptosis, is characterized by the expansion of a population of double-negative CD4–CD8-mature T cells that enlarges the paracortex of lymph nodes and may mimic PTCL because of its aberrant phenotype.[142] The associated clinical circumstances of autoimmune cytopenias often present, the pediatric age group, and the presence of circulating lymphocytes with the aberrant double-negative immunophenotype with increased CD57-positive T cells are useful hints to the correct diagnosis. Necrotizing lymphohistiocytic lymphadenitis (Kikuchi's disease) comprises a paracortical expansion of activated cytotoxic T cells and histiocytes that is morphologically atypical and may be confused with PTCL.[143,144] The morphologic features and criteria of these diseases are thoroughly described in **Chapters 53** and **8**, respectively.

Peripheral T-Cell Lymphoma, Not Otherwise Specified With Reed-Sternberg–Like Cells

Large lymphoid cells with RS-like morphology are found frequently in PTCL, NOS. These cells are either part of the neoplastic clone or represent EBV-positive bystander B cells, and by immunohistochemistry may be positive for CD30, or even occasionally positive for both CD30 and CD15. These findings may raise the differential diagnoses with classic Hodgkin lymphoma, reactive EBV-positive lymphoproliferation (infectious mononucleosis), T-cell/histiocyte-rich large B-cell lymphoma, and AITL (**Table 34-3**).

Lymphoepithelioid Variant of Peripheral T-Cell Lymphoma, Not Otherwise Specified (Lennert

Lymphoma)

This variant must be distinguished from other conditions associated with a prominent epithelioid infiltrate: reactive granulomatous conditions, classic Hodgkin lymphoma, mixed cellularity,[145] T-cell/histiocyte–rich large B-cell lymphoma, lymphoplasmacytic lymphoma with a high content of epithelioid cells,[146] and TFH lymphoma with a high content of epithelioid cells (**Table 34-3**).[147] Indeed, a reappraisal of Lennert's personal collection revealed that many cases previously categorized as lymphoepithelioid/Lennert lymphoma in fact represent examples of histiocyte-rich TFH lymphoma of angioimmunoblastic type or NOS.[105,106]

CD30-Positive Peripheral T-Cell Lymphoma, Not Otherwise Specified

PTCL, NOS occasionally displays strong and homogeneous expression of CD30 in most neoplastic cells, and in those instances, differential diagnosis with ALCL, ALK negative constitutes a major challenge. The distinction is of clinical relevance because ALCL, ALK negative is associated with a better prognosis than PTCL, NOS.[148] *DUSP22* rearrangements recently described in association with ALK-negative ALCL, have not been found in PTCL, NOS, and may represent a useful adjunct to the diagnosis.[149] Another area of confusion is between CD30-positive PTCL, NOS and classic Hodgkin lymphoma, inasmuch as CD30-positive PTCL, NOS occasionally co-expresses CD15. The distinguishing features that are useful to consider in these settings are summarized in **Table 34-4**.

Table 34-3

EBV, Epstein-Barr virus; *PTCL, NOS,* peripheral T-cell lymphoma, not otherwise specified; *RS,* Reed-Sternberg; *TFH,* T-follicular helper cell.

Table 34-4

+, Nearly always positive; −/+, usually negative, may be positive; +/−, usually positive, may be negative; *EBV,* Epstein-Barr virus; *EMA,* epithelial membrane antigen; *PTCL, NOS,* peripheral T-cell lymphoma, not otherwise specified; *RS,* Reed-Sternberg.

Pearls and Pitfalls

- Peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS) is a "by default" entity, which requires exclusion of other potential diagnoses. Notably, because the diagnosis of follicular helper T-cell (TFH) lymphoma has been expanding, the prevalence of PTCL, NOS in recent registries is decreasing.
- A T-cell aberrant immunophenotype is indicative of malignancy and present in most cases of PTCL, NOS. High-throughput sequencing is a useful adjunct to other ancillary studies to guide the diagnosis of PTCL, NOS, and potentially to inform therapeutic decisions.
- Two molecular subgroups of PTCL, NOS—TBX21 and GATA3—defined by their gene-expression signature, correspond to

distinct pathogenic pathways and outcomes, and can be approached by an immunohistochemistry algorithm.
